(Received 5 April 2009; published 5 June 2009)

We investigate how quantum coincidence interferometry is affected by a controllable manipulation of transverse wave vectors in type-II parametric down-conversion using adaptive optics techniques. In particular, we discuss the possibility of spatial walk-off compensation in quantum interferometry and an effect of even-order spatial aberration cancellation.

DOI: 10.1103/PhysRevA.79.062304 PACS number(s): 03.67.Bg, 42.50.St, 42.50.Dv, 42.30.Kq

I. INTRODUCTION

Quantum entanglement [1] is a valuable resource in many areas of quantum optics and quantum information processing. One of the most widespread techniques for generating entangled optical states is spontaneous parametric down-conversion (SPDC) [2–5]. SPDC is a second-order nonlinear optical process in which a pump photon is split into a pair of new photons with conservation of energy and momentum. The phase-matching relation establishes conditions to have efficient energy conversion between the pump and the down-converted waves, called signal and idler. This condition also sets a specific relation between the frequency and the emission angle of down-converted radiation. In other words, the quantum state emitted in the SPDC process cannot be factorized into separate frequency and wave-vector components. This leads to several interesting effects where the manipulation of a spatial variable affects the shape of the polarization-temporal interference pattern. For example, the dependence of polarization-temporal interference on the selection of collected wave vectors was studied in detail in [6].

Here we engineer the quantum state in the space of transverse momentum and we study how this spatial modulation is transferred to the polarization-spectral domain by means of quantum interferometry. We will focus on type-II SPDC using birefringent phase matching since the correlations between wave vectors and spectrum are stronger than those employing other phase-matching conditions.

Our aim is twofold. From one point of view, we study the effect of spatial modulations on temporal quantum interference. This could be useful, for example, in quantum optical coherence tomography (QOCT) [7,8]. When focusing light on a sample with nonplanar surface, the photons will acquire a spatial phase distribution in the far field, which may perturb the shape of the interference dip. Our results will provide a tool to understand this effect.

From a second point of view, we would like to study and characterize spatial modulation as a tool for quantum state engineering. This may find application in the field of quantum information processing, where it is important to gain a high degree of control over the production of quantum entangled states entangled in one or more degrees of freedom (hyperentanglement).

We start by introducing a theoretical model of a type-II quantum interferometer, comprising the polarization, spectral, and spatial degrees of freedom (Sec. II). A modulation in the wave-vector space is provided by an adaptive optical setup and equations for the polarization-temporal interference pattern in the coincidence rate are derived. In Sec. III, we introduce a numerical approach for practical evaluation of the results of the theoretical model, discussing a few examples for general spatial aberrations.

In Sec. IV we will highlight and discuss theoretically two interesting special cases. The first one is the possibility of restoring high visibility in type-II quantum interference with large collection apertures. In some situations, to collect a higher photon flux or a broader photon bandwidth, it can be useful to enlarge the collection apertures of the optical system. But when dealing with type-II SPDC in birefringent crystals, for large collection apertures the effect of spatial walkoff introduces distinguishability between the photons, leading to a reduced visibility of temporal and polarization quantum interference. We will show that high visibility can be restored with a linear phase shift along the vertical axis.

The second effect is the spatial counterpart of spectral dispersion cancellation [9,10]. In the limit of large detection apertures, the correlations between the photons’ momenta will cancel out the effects of even-order aberrations, exactly as in the limit of slow detectors the frequency correlations cancel out the even-order terms of spectral dispersion. The experimental demonstration of this effect has been reported recently [11].

As we proceed from the general case of Secs. II and III into the specific examples of Sec. IV, we will gradually see that optical aberration is a subject with two very different faces. On one hand, aberrations in optical components are normally seen as undesirable, since they lead to distortions in imaging. We will see that these unwanted spatial modulations may to some extent be canceled. On the other hand, we will find that such spatial modulations may also be turned into a useful tool: by deliberately introducing spatial modulations (in effect, purposely adding aberrations in a controlled manner), we can produce useful effects such as the restoration of visibility mentioned above. The examples we provide in Sec. IV will illustrate these two aspects and will show that both can benefit from more detailed study of the interplay between spatial modulations and spectral correlations.
An aperture is placed before the beam splitter to select an\nbetween the detection events of the two detectors is recorded.

The wave number is \( q = \frac{n(\Omega)k}{v} \).

\( A. \) Notation

Consider a monochromatic plane wave of complex ampli-
tude \( E(r, t) = E_0 e^{i k r} \), with \( r = (x, y, z) \). For a given wavelength \( \lambda \), corresponding to a frequency \( \Omega \), the wave can be split into a transverse component \( q = (q_x, q_y) \) and a longitudi-
nal component \( \beta(q, \Omega) \):

\( k = [q, \beta(q, \Omega)] \).

The wave number is

\( k(\Omega) = \frac{n(\Omega)k}{c} \).

The longitudinal component of the wave vector is

\( \beta(q, \Omega) = \sqrt{k^2(\Omega) - |q|^2} \).

Therefore the electric field at the position \( r \) and time \( t \) can be written as

\( E(r, t) = \int dq \int d\Omega \epsilon(q, \Omega) e^{-iq \cdot \rho} e^{-i\beta(q, \Omega) \cdot \rho} \epsilon d\Omega \).

where \( \rho = (x, y) \).

In paraxial approximation \( |q|^2 \ll k^2(\Omega) \), so that

\( \beta(q, \Omega) \approx k(\Omega) - \frac{|q|^2}{2k(\Omega)} \).

For a quasimonochromatic wave packet centered around the
frequency \( \Omega_0 \), one can write \( \Omega = \Omega_0 + \nu \), with \( \nu \ll \Omega_0 \). This
expression can be approximated by

\( \beta(q, \Omega) \approx k_0 + \nu \frac{u_0}{k_0} - \frac{|q|^2}{2k_0} \).

where \( k_0 = k(\Omega_0) \) and \( u_0 = \frac{d(k(\Omega))}{d\Omega} \mid_{\Omega = \Omega_0}^{-1} \) is the group velocity
for the propagation of the wave packet through the material.

B. State generation

Using first-order time-dependent perturbation theory, the
two-photon state at the output of the nonlinear crystal can be calculated as

\( \psi(\Omega) = \frac{i}{\hbar} \int dt H(t)|0\rangle \).

where the interaction Hamiltonian is

\( H(t) = \frac{1}{\sqrt{V}} \int d\mathbf{r} \chi^{(2)}(\mathbf{r}) E_p^*(\mathbf{r}, t) E_1(\mathbf{r}, t) E_1(\mathbf{r}, t) \).

The strong, undepleted pump beam can be treated classically.
Assuming a monochromatic plane wave propagating along
the \( z \) direction,

\( E_p(\mathbf{r}, t) = E_0 e^{ik_p z} \).

The signal and idler photons are described by the following
quantum field operators:

\( \hat{E}_j(\mathbf{r}, t) = \int dq d\omega e^{i\beta(q, \omega) z - q \cdot \rho} \hat{a}(\mathbf{q}, \omega) \).

where \( j = e, o \).

The biphonon quantum state at the output plane of the nonlinear crystal is [12]

\( |\psi(\Omega_0, \nu)\rangle = \int dq d\omega e^{-i\beta(q, \omega) z - q \cdot \rho} \hat{a}(\mathbf{q}, \omega) |0\rangle \).

Two photons are emitted from the nonlinear crystal, one
horizontally polarized (ordinary photon) and the other verti-
cally polarized (extraordinary photon), with anticorrelated
frequencies and emission directions.

In the case of a single bulk crystal of thickness \( L \) and
constant nonlinearity \( \chi_n \), the probability amplitude for having
the signal photon in the mode \( (\mathbf{q}, \Omega_0 + \nu) \) and the idler in the
mode \( (-\mathbf{q}, \Omega_0 - \nu) \) is

\( \Phi(q, \nu) = \left| \frac{L \Delta(q, \nu)}{2 \pi} \right|^2 e^{i\Delta(q, \nu) L/2} \).

where \( \Delta(q, \nu) = \Omega_0 - \nu \). For type-II collinear degenerate phase matching, the phase-
 mismatch function \( \Delta(q, \nu) \) can be approximated to be

062304-2
\[ \Delta(q, \nu) = -\nu D + M\hat{e}_2 \cdot q + \frac{2|q|^2}{k_p}, \]  

where \( D \) is the difference between the inverse of the group velocities of the ordinary and extraordinary photons inside the birefringent crystal and the quadratic term in \( q \) is due to diffraction in paraxial approximation. The remaining term is the first-order approximation for the spatial walkoff.

### C. Propagation

Consider a photon described by the operator \( \hat{a}_i(q, \Omega) \) (polarization \( j=e, o \), frequency \( \Omega \), and transverse momentum \( q \)). Its propagation through an optical system to a point \( x_\lambda \) on the output plane is described by the optical transfer function \( H_j(x_\lambda, q; \Omega) \). In our setup, the field at the detector will be a superposition of contributions from the ordinary and extraordinary photons. The quantized electric fields at the detector planes are

\[
\hat{E}^{(e)}_j(x_\lambda, t_A) = \int dq \int d\omega \text{e}^{i\omega t_A} \left[ H_j(x_\lambda, q; \omega) \hat{a}_j(q, \omega) ight],
\]

\[
\hat{E}^{(o)}_j(x_B, t_B) = \int dq \int d\omega \text{e}^{i\omega t_B} \left[ H_j(x_B, q; \omega) \hat{a}_j(q, \omega) ight].
\]

The probability amplitude for detecting a photon pair at the detector planes, with space-time coordinates \( (x_\lambda, t_A) \) and \( (x_B, t_B) \), is

\[
A(x_\lambda, x_B; t_A, t_B) = \langle 0 | \hat{E}^{(e)}_j(x_\lambda, t_A) \hat{E}^{(o)}_j(x_B, t_B) | \psi \rangle.
\]

For the biphoton probability amplitude we get

\[
A(x_\lambda, x_B; t_A, t_B) = \int dq dq_e dq_o dq_o e^{\omega_o t_B} \Phi(q, q_e; \omega_o, \omega_o) \times \left[ H_j(x_\lambda, q; \omega) H_j(x_B, q; \omega) e^{-i(\omega_o t_A + \omega_o t_B)} ight. \
\left. + H_j(x_\lambda, q_o; \omega_o) H_j(x_B, q_e; \omega) e^{-i(\omega_o t_A + \omega_o t_B)} \right].
\]

This probability amplitude represents the superposition of two possible events leading to a coincidence count in the detectors:

1. The V polarized photon with momentum \( q_e \) and frequency \( \omega_o \) going through the lower branch to arrive at position \( x_\lambda \) in detector \( A \); while the H polarized photon with momentum \( q_o \) and frequency \( \omega_o \) goes through the upper branch to arrive at position \( x_B \) in detector \( B \); and

2. The V polarized photon with momentum \( q_e \) and frequency \( \omega_o \) going through the lower branch to arrive at position \( x_B \) in detector \( B \); while the H polarized photon with momentum \( q_o \) and frequency \( \omega_o \) goes through the upper branch to arrive at position \( x_\lambda \) in detector \( A \).

Since the superposition is coherent, there are quantum-interference effects between the two probability amplitudes.

### 1. State engineering section

In the state engineering section, each of the two branches consists of a pair of achromatic Fourier-transform systems coupled by a spatial light modulator or a deformable mirror. Each Fourier-transform system consists of a single lens of focal length \( f \), separated from the optical elements before and after it by a distance \( f \). The first Fourier system maps each incident transverse wave vector \( q \) on the plane \( \Pi_{in} \) to a point \( x(q) \) on the Fourier plane \( \Pi_{out} \):

\[
x(q) = \frac{f}{k_0} q, \quad k_0 = \frac{\Omega_0}{c}, \tag{17}
\]

where \( f \) is the focal length of the Fourier-transform system. Since we assume that the system is achromatic for a certain bandwidth around a central frequency \( \Omega_0 \), the position \( x(q) \) depends only on \( q \) and not on \( \omega \).

The spatial modulator assigns a different amplitude and phase to the light incident on each point, as described by the function \( G(x) = i(x/c)e^{i\phi(x)} \). Each point is then mapped back to a wave vector on the plane \( \Pi_{out} \) by the second achromatic Fourier-transform system.

Using the formalism of Fourier optics [13], the transfer function between the planes \( \Pi_{in} \) and \( \Pi_{out} \) can be calculated to be

\[
h_1(x_1, x_2) = \int dx G(x) e^{-i(k_0/f)x(x_1 + x_2)}, \tag{18}
\]

The corresponding momentum-transfer function is

\[
H_1(q_1, q_3) = G \left[ \frac{f}{k_0} q_1 \right] \delta(q_1 - q_3). \tag{19}
\]

### 2. Interferometer

After the plane \( \Pi_{out} \) the two photons enter a type-II quantum interferometer. Each propagates in free space to a birefringent delay line and a detection aperture \( p(x) \) to be finally focused to the detection planes by means of lenses of focal length \( f_0 \). Following the derivation in [6] the transfer function is

\[
H_2(x_i, q; \omega) = \int dx h(x_i, x_i; \omega) e^{iqx_i} \delta(x_1 - x_i),
\]

\[
= e^{i(\omega/c)(d_1 + d_2 + f_0)} \exp \left[ \frac{-iD x_i^2}{2cf_0} \left( \frac{d_2}{f_0} - 1 \right) \right] \times e^{-i(c/d_1/2)q^2/\Omega} \left( \frac{\omega}{cf_0} \right) x_i - q), \tag{20}
\]

where \( \tilde{p}(q) \) is the Fourier transform of \( |p(x)|^2 \).

A combination of the two different stages is described by the transfer function

\[
H_j(x_j, q; \omega) = G_j \left[ \frac{f}{k_0} q_j \right] H_2(x_j, q; \omega), \tag{21}
\]

where the two functions \( G_j(q) \) and \( H_j(q) \) are the momentum-transfer functions which describe the modulation.
impacted, respectively, on the ordinary and the extraordinary photons.

**D. Detection**

Since the single-photon detectors used in quantum optics experiments are slow with respect to the temporal coherence of the photons and their area is larger than the spot onto which the photons are focused by the collection lens, we integrate over the spatial and temporal coordinates. Therefore the coincidence count rate expressed in terms of the biphoton probability amplitude is

\[ R(\tau) = \int dx_A \int dx_B \int dt_A \int dt_B |A(x_A, x_B; t_A, t_B)|^2. \]  

(22)

Following the derivation described in Appendix A, one gets

\[ R(\tau) = R_0 \left[ 1 - \lambda \left( 1 - \frac{2\tau}{DL} \right) W_M(\tau) \right], \]  

(23)

where \( \lambda(x) \) is the triangular function

\[ \lambda(x) = \begin{cases} 1 - |x|, & |x| \leq 1 \\ 0, & |x| > 1. \end{cases} \]  

(24)

Therefore, the coincidence count rate \( R(\tau) \) is given by the summation of a background level \( R_0 \) and an interference pattern given by the triangular dip \( \lambda(1 - \frac{2\tau}{DL}) \) that one gets when working with narrow apertures, modulated by the function \( W_M(\tau) \) which depends on the details of the adaptive optical system.

The expressions for \( R_0 \) and \( W_M(\tau) \) are

\[ R_0 = \int dq \int dq' \text{sinc}[ML\hat{e}_2 \cdot (q - q')] \times G_1' \left( \frac{f}{k_0} q \right) G_1 \left( \frac{f}{k_0} q' \right) G_2' \left( - \frac{f}{k_0} q \right) \times G_2 \left( - \frac{f}{k_0} q' \right) e^{-i(ML/2)q_2(q-q')} e^{i(2d_1/k_0)|q|^2 - |q'|^2} \times \tilde{P}_A(q - q') \tilde{P}_B(-q + q') \]  

(25)

and

\[ W_M(\tau) = \frac{1}{R_0} \int dq \int dq' \text{sinc} \left[ ML\hat{e}_2 \cdot (q + q') \lambda \times \left( 1 - \frac{2\tau}{DL} \right) \right] G_1' \left( \frac{f}{k_0} q \right) G_1 \left( \frac{f}{k_0} q' \right) G_2' \left( - \frac{f}{k_0} q \right) \times G_2 \left( - \frac{f}{k_0} q' \right) e^{-i(ML/2)q_2(q+q')} e^{i(2d_1/k_0)|q|^2 - |q'|^2} \times \tilde{P}_A(q + q') \tilde{P}_B(-q + q'). \]  

(26)

In the following we will assume there is spatial modulation only on one of the photons; therefore we set \( G_2(q) = 1. \)

**III. NUMERICAL SOLUTIONS FOR A GENERAL PHASE SHIFT**

Numerically solving for the quantities in Eqs. (25) and (26) in the case of a general aberration may be computationally demanding. Here, we propose an approximation, valid in the case where the function \( G(x) \) changes smoothly over the mirror surface, as it is the case in experimentally relevant situations. This model is also interesting from the practical point of view, since in many cases adaptive optical systems are implemented using spatial light modulators or segmented deformable mirrors, where the modulation surface is partitioned into small pixels.

Suppose we partition the Fourier plane \( \Pi_F \) into small squares (pixels) of side \( d \) (Fig. 2). Let us define the rectangular function

\[ \Pi(x) = \begin{cases} 0 & \text{if } |x| \geq \frac{d}{2} \\ 1 & \text{if } |x| < \frac{1}{2}. \end{cases} \]  

(27)

The pixel \((l, m)\) is identified by

\[ \sigma_{lm}(x, y) = \Pi \left[ \frac{x}{d} + l \right] \Pi \left[ \frac{y}{d} + m \right], \]  

(28)

selecting the area

\[(l - \frac{1}{2})d < x < (l + \frac{1}{2})d, \frac{1}{2}d < y < (m + \frac{1}{2})d, \]
Performing the integrations one gets
\[
\int \frac{dx}{d}y \varphi(x,y) = \int \frac{dx}{d}y \varphi(x,y) \Pi \left[ \frac{x}{d} + l \right] \Pi \left[ \frac{y}{d} + m \right].
\]
(30)
That is,
\[
\varphi_{lm} = \frac{1}{d^2} \int dx dy \varphi(x,y) \Pi \left[ \frac{x}{d} + l \right] \Pi \left[ \frac{y}{d} + m \right].
\]
(31)
In this case (see Appendix B for a justification)

Substituting this expression into Eq. (23) and collecting the integrations, one finds
\[
R(\tau) = \sum_{l,m} \sum_{\lambda,\mu} e^{-i \phi_{lm} - \phi_{\lambda,\mu}} \alpha_{\lambda,\mu} I_{\lambda,\mu}(\tau),
\]
(33)
where

\[
\alpha_{\lambda,\mu} = \int dq_x \int dq_y \Pi \left[ \frac{f_x}{kd} q_x - l \right] \Pi \left[ \frac{f_y}{kd} Q_y - \lambda \right] e^{i(2d_1/k_p)(q_x - Q_x)^2} e^{iQ_x + Q_y} e^{-iQ_x + Q_y} e^{-i2\tau} M \left[ q_x + Q_y \right] P \left[ q_x + Q_y \right].
\]
(34)
Performing the integrations one gets
\[
\alpha_{\lambda,\mu} = \int dx \bar{P}(x) \Lambda \left[ \frac{f_x}{kd} x - (l + \lambda) \right] \left[ \frac{f_y}{kd} Q_y - \lambda \right] e^{i(2d_1/k_p)(q_x - Q_x)^2} e^{iQ_x + Q_y} e^{-iQ_x + Q_y} e^{-i2\lambda} x.
\]
(36)
and
\[
I_{\lambda,\mu}(\tau) = \int dq_x \int dq_y \Pi \left[ \frac{f_x}{kd} q_x - l \right] \Pi \left[ \frac{f_y}{kd} Q_y - \lambda \right] e^{i(2d_1/k_p)(q_x - Q_x)^2} e^{iQ_x + Q_y} e^{-iQ_x + Q_y} e^{-i2\lambda} x.
\]
(37)
A similar expression can be found for the background coincidence rate:
\[
R_0 = \sum_{l,m} \sum_{\lambda,\mu} e^{-i \phi_{lm} - \phi_{\lambda,\mu}} R_{\lambda,\mu}^{(\lambda,\mu)}(\tau),
\]
(38)
where
\[
R_{\lambda,\mu}^{(\lambda,\mu)} = \int dx \bar{P}(x) \Lambda \left[ \frac{f_x}{kd} x - (l + \lambda) \right] \left[ \frac{f_y}{kd} Q_y - \lambda \right] e^{i(2d_1/k_p)(q_x - Q_x)^2} e^{iQ_x + Q_y} e^{-iQ_x + Q_y} e^{-i2\lambda} x.
\]
(39)
and
\[
R_{\lambda,\mu}^{(\lambda,\mu)} = \int dx \bar{P}(x) \Lambda \left[ \frac{f_x}{kd} x - (m + \mu) \right] \left[ \frac{f_y}{kd} Q_y - \lambda \right] e^{i(2d_1/k_p)(q_x - Q_x)^2} e^{iQ_x + Q_y} e^{-iQ_x + Q_y} e^{-i2\lambda} x.
\]
(40)

The advantage of our numerical approach is that one can calculate and tabulate the functions \( R_{\lambda,\mu}^{(\lambda,\mu)} \), \( \alpha_{\lambda,\mu} \), and \( I_{\lambda,\mu}(\tau) \) for a given configuration, determined by the focal length, the shape of the detection apertures, the width of the deformable optics, and the distance between the crystal and the detectors. Then, to calculate the shape of the interference pattern for a certain phase distribution on the adaptive optics, one just needs to change the coefficient of a linear combination of the tabulated functions. This can be a helpful tool for studying the effect of specific aberrations on the temporal
interference or to engineer the shape of the Hong-Ou-Mandel (HOM) dip.

Some examples of how the temporal quantum-interference dip is modulated by a generic spatial phase shift are reported in Fig. 3, for coma (upper plot) and a superposition of several different aberrations (lower plot). The interference visibility clearly degrades in presence of wave-front aberrations.

IV. PARTICULAR CASES

In this section we will discuss the quantum-interference pattern, described by Eq. (23), for a few simple cases. First we will consider the case when no spatial modulation is assigned to the photons and Eq. (23) will reduce to the results already described in the literature for quantum interferometry with multiparametric entangled states from type-II downconversion [6]. Then we will examine the effect of a linear superposition of aberrations affects dramatically the shape of the dip.

A. No phase modulation

Applying no phase modulation, our equations reduce to the ones derived in [6]. Particularly we find

\[ R_0 = \tilde{P}_A(0)\tilde{P}_B(0) \]  \hspace{1cm} (41)

and

\[ W_C(\tau) = \text{Sinc} \left[ \frac{M^2Lk_p}{2d_1D} \tau \left( 1 - \frac{2\tau}{DL} \right) \right] \tilde{P}_A \times \left[ \frac{Mk_p}{2d_1D} \tau e_2^1 \right] \tilde{P}_B \left( -\frac{Mk_p}{2d_1D} \tau e_2^1 \right). \]  \hspace{1cm} (42)

The shape of the interference pattern is essentially given by the product of the triangular function by the Fourier transform of the aperture function, centered at \( \tau = 0 \). For physically relevant parameters the sinc function is almost flat in the region where the triangular function is not zero.

To get an analytic result one may assume Gaussian detection apertures of radius \( R_G \) centered along the system’s optical axis:

\[ \rho(x) = e^{-|x|^2/R_G^2}. \]  \hspace{1cm} (43)

In this case the solution is quite simple:

\[ R(\tau) = R_0 \left[ 1 - \Lambda \left( 1 - \frac{2\tau}{DL} \right) e^{-\tau^2/2 \tau^2} \right]. \]  \hspace{1cm} (44)

with

\[ \tau_1 = \frac{2d_1D}{k_pMR_G}. \]  \hspace{1cm} (45)

Typically, sharp circular apertures are used in experiments. In this case, the function \( \tilde{P}([\mathbf{q}]) \) is described in terms of the Bessel function \( J_1(x) \). For a circular aperture of radius \( R \),

\[ \tilde{P}([\mathbf{q}]) = \frac{J_1(2R|\mathbf{q}|)}{R|\mathbf{q}|}. \]  \hspace{1cm} (46)

However the Gaussian approximation is still a good one if the width \( R_G \) of the Gaussian is taken to roughly fit the Bessel function (of width \( R \)): in our case we take \( R_G = R/(\sqrt{2}) \).

Therefore Eq. (44) is still approximately valid in the case of sharp circular apertures, just taking

\[ \tau_1 = \frac{4\sqrt{2}d_1D}{k_pMR_B}. \]  \hspace{1cm} (47)

Mathematically, in Eq. (44) the interference pattern is given by the multiplication of a triangular function centered at \( \tau = DL/2 \) by a Gaussian function centered at \( \tau = 0 \). The width of the Gaussian function \( \tau_1 \) decreases with increasing radius of the aperture \( R_B \). Therefore, in the small-aperture approximation, the width of the Gaussian is so large that it is approximately constant between \( \tau = 0 \) and \( \tau = DL/2 \), giving the typical triangular dip found in quantum-interference experiments. On the other hand, increasing the aperture size, the width of the Gaussian function decreases, reducing the dip visibility (see Fig. 4). Physically, this can be explained by the fact that by increasing the aperture size we let more wave vectors into the system, and so the spatial walkoff in type-II interferometry introduces distinguishability, reducing
the interference visibility. Enlarging the aperture sizes is often useful in practice, for example, to get a higher photon flux. Moreover, since in the SPDC process different frequency bands are emitted at different angles, it may be necessary to open the detection aperture in applications where a broader bandwidth is needed. This is clearly a problem when using type-II phase matching in birefringent crystals, since the visibility of temporal and polarization interference gets drastically reduced.

B. Linear phase shift

Suppose now we introduce a linear phase function with the spatial light modulator, along the direction $s_1$,

$$\varphi(x) = s_1 \cdot x,$$

we get

$$W_M(\tau) = \text{Sinc} \left[ \frac{M^2 k_0}{2d_1 D} \tau \Lambda \left( 1 - \frac{2\tau}{DL} \right) \hat{P}_A \right]$$

$$\times \left[ \frac{Mk_0}{2d_1 D} \hat{e}_2 + 2f s_1 \right] \hat{P}_B - \frac{Mk_0}{2d_1 D} \hat{e}_2 - 2f s_1 \right].$$

(49)

If we compare Eq. (49) with Eq. (44) we can see that the structure is the same. We again have a triangular function centered at $\tau=DL/2$, along with two aperture functions. But this time, instead of being centered at $\tau=0$, the aperture functions can be shifted at will along the $\tau$ axis. Suppose we now apply a tilt along the $y$ axis ($s_{1y} = 0$). The modulation function is then shifted to

$$\tau_{\text{center}} = \frac{fD}{k_0 M} s_{1y}.$$

(50)

To get the highest possible visibility, the center of the modulation function must be matched to the center of the triangular dip,

$$\tau_{\text{center}} = \frac{DL}{2},$$

(51)

so that

$$s_{1y} = \frac{k_0 M L}{2f}.$$

(52)

In the case of a reflective system, in which the phase modulation is implemented by means of a deformable mirror (Fig. 5), tilted by an angle $\theta$,

$$\varphi(x) = 2k_0 \tan \theta y = s_{1y} y.$$

(53)

Therefore, the amount of tilt necessary to restore high visibility is

$$\tan \theta = \frac{ML}{4f}.$$  

(54)

In the case of a 1.5 mm crystal, with $M = 0.0723$ (pump at 405 nm, SPDC at 810 nm) and lenses with focal length of 20 cm in the 4$f$ system, we get

$$\theta = 0.14 \text{ mrad}.$$  

(55)

C. Large-aperture approximation

If the detection apertures are large enough for the $\hat{P}_t$ function to be successfully approximated by a delta function, we get

$$W_M(\tau) = \int d\mathbf{q} G_1 \left( \frac{\mathbf{f}}{k_0} \mathbf{q} \right) \hat{G}_1 \left( -\frac{\mathbf{f}}{k_0} \mathbf{q} \right) e^{-i(2ML)\hat{e}_2 \cdot \mathbf{q}}.$$  

(56)

Suppose that the spatial modulator is a circular aperture with radius $r$, with unit transmission and phase modulation described by the function $\varphi(x)$,

$$G_1(x) = \begin{cases} 0 & \text{if } |x| > r \\ e^{i\varphi(x)} & \text{if } |x| < r. \end{cases}$$

(57)

In this case the function $\varphi(x)$ can be expanded on a set of polynomials which are orthogonal on the unit circle, such as the Zernicke polynomials:

$$\varphi(\mathbf{q}) = \sum_n \sum_m \varphi_{nm} R_n^m(\rho) \cos(m\theta),$$

where

$$R_n^m(\rho) = \sum_{l=0}^n \frac{(-1)^l}{l!} \frac{\rho^{2l}}{(2l+1)} \frac{\partial^{2l}}{\partial \rho^{2l}} \frac{(\rho^2 - 1)^m}{(2l+1)C_{l,m}}.$$
of this effect was recently reported in the spectral phase survive. The experimental demonstration spatial counterpart of the dispersion cancellation effect, in to the shape of the interference pattern. This effect is the BONATO et al. = 25/H9262 apertures is tween the exit plane of the modulation section and the detection

\[ m = -n, -n + 2, -n + 4, \ldots, n, \quad (58) \]

where \( q = (\rho \cos \theta, \rho \sin \theta) \). To calculate \( \varphi(-q) \) we note that 

\[ \varphi(-q) = \sum_n \sum_m R_m^0(\rho) \cos[m(\theta + \pi)]. \quad (59) \]

If \( m \) is even then \( \cos[m(\theta + \pi)] = \cos(m\theta) \); otherwise if \( m \) is odd \( \cos[m(\theta + \pi)] = -\cos m\theta \). Therefore

\[ \varphi(q) - \varphi(-q) = 2 \sum_n \sum_{m \text{ odd}} \varphi_{nm} R_m^0(\rho) \cos(m\theta). \quad (60) \]

So, only the Zernicke polynomials with \( m \) odd contribute to the shape of the interference pattern. This effect is the spatial counterpart of the dispersion cancellation effect, in which only the odd-order terms in the Taylor expansion of the spectral phase survive. The experimental demonstration of this effect was recently reported in [11].

An interesting question is how large the detection apertures should effectively be, in order to obtain the even-order aberration cancellation effect. According to the numerical approach proposed in Sec. IV, the even-order aberration cancellation effect manifests itself in the limit where \( R(\lambda) = \delta(\lambda) \), so that

\[ \alpha_{l,\lambda} \to \delta(l + \lambda). \quad (61) \]

In Fig. 6, a plot of the value for \( \alpha_{l,\lambda} \) is shown for typical values of the relevant experimental parameters (detection aperture radius \( R = 5 \) mm, detection distance \( d_1 = 1 \) m, and size \( d = 0.1 \) mm of each pixel in the Fourier plane of the adaptive optical system). Clearly, only the diagonal elements (the ones for which \( l = -\lambda \)) are significant, suggesting that the effect of even-order aberration cancellation may be observable for most typical experimental parameters.

To get an idea of what happens for different experimental conditions, we can compute the ratio between the intensities

\[ \frac{R^0_{00}}{R^0_{01}} = \frac{|\alpha_{01}|^2}{|\alpha_{00}|^2}. \quad (62) \]

The lower the value for \( \rho_0 \) is, the less significant the coefficients for \( \lambda \neq -l \) are: the even-order aberration cancellation effect will therefore manifest itself more clearly.

Values for \( \rho_0 \) are shown in Fig. 7 for two different cases. In both pictures, the value of \( \rho_0 \) is shown as a function of the Gaussian detection aperture radius \( R \), for three different values of the distance between the plane \( H_3 \) and the detection lenses \( d_1 \). In the upper panel, the size of each small square in which the spatial phase is assumed to be constant is \( d = 0.5 \) mm, while in the second case it is \( d = 0.25 \) mm. Clearly, for experimentally interesting cases, the off-diagonal coefficient is at least 3 orders of magnitude smaller than the diagonal one, leading to even-order aberration cancellation.

![Plot of the ratio \( \rho_0 \) between the intensities of the nondiagonal coefficient \( \alpha_{01} \) and the diagonal coefficient \( \alpha_{00} \) as a function of the radius of Gaussian detection apertures, \( R \), for different values of the distance between the exit plane of the modulation section and the detection apertures \( (d_1=1,10,100 \) cm). On the upper plot the size of the modulation pixel \( d \) is \( d=0.5 \) mm, while in the second case it is \( d=0.25 \) mm. Clearly, for experimentally interesting cases, the off-diagonal coefficient is at least 3 orders of magnitude smaller than the diagonal one, leading to even-order aberration cancellation.](Image 88x608 to 256x741)
MULTIPARAMETER ENTANGLED-STATE ENGINEERING...  

PHYSICAL REVIEW A 79, 062304 (2009)

V. CONCLUSIONS

Summarizing, in this paper we have carried out a theoretical study of the relation between the wave-front modulation of the entangled SPDC photons and the shape of the resulting temporal quantum-interference pattern. Due to the multiparametric nature of the generated entangled states, the modulation on the spatial degree of freedom can affect the shape of the polarization-temporal interference pattern in the coincidence rate. Our aim is twofold: from one side we want to study the effect of wave-front aberration on quantum interferometry, and from the other we want to discuss a way to engineer multiparametrically entangled states.

We have introduced a theoretical model for calculation of the shape of the polarization-temporal interference pattern given a certain general phase modulation in the crystal far field, assuming as a free parameter the shape and the dimension of the collection apertures. Using a numerical method to study the resulting equation has shown that for typical experimental cases the hypothesis of large apertures can be assumed to be valid. In such an approximation, only the odd part of the assigned phase modulation affects the shape of the interference pattern. This effect has recently been demonstrated experimentally [11].

Moreover, it is often useful in experiments to enlarge the collection aperture in order to collect a higher photon flux and larger optical bandwidth. But when working with type-II birefringently phase-matched down-conversion, spatial walkoff between the emitted photons introduces distinguishability between the two possible events that can lead to coincidence detection, reducing the visibility of quantum interference. Such walkoff can be compensated for with a linear phase shift in the vertical direction, restoring high visibility.

APPENDIX A: SKETCH OF DERIVATION OF EQ. (23)

In this appendix we sketch the major steps for the derivation of Eq. (23). Substituting Eq. (21) into Eq. (16) and the result into Eq. (22), one finds the following expressions for $R_0$ and $W^{(i)}(\tau)$:

\[
R_0 = \int dq\, dq' \, d\tau \Phi(q, v) \Phi(q', v) G_{21} \left[ \frac{f}{k} q' \right] \left[ \frac{f}{k} q \right] \left[ G_{12} - \frac{f}{k} q' \right] \left[ G_{22} - \frac{f}{k} q' \right] W^{(i)}(q, q', v), \tag{A1}
\]

\[
W^{(i)}(\tau) = \frac{1}{R_0} \int dq\, dq' \, d\tau \Phi(q, v) \Phi(q', -v) G_{21} \left[ \frac{f}{k} q' \right] \left[ \frac{f}{k} q \right] \left[ G_{12} - \frac{f}{k} q' \right] \left[ G_{22} - \frac{f}{k} q' \right] W(q, q', v), \tag{A2}
\]

where

\[
W^{(i)}(q, q', v) = \int dx_\alpha dx_\beta H^*(x_\alpha, q, v) H(x_\beta, q, -v) H(x_\alpha, q', v) H(x_\beta, q', -v) \tag{A3}
\]

\[
W(q, q', v) = \int dx_\alpha dx_\beta H^*(x_\alpha, q, v) H(x_\beta, q, -v) H(x_\alpha, q', v) H(x_\beta, q', -v) \tag{A4}
\]

The angular and spectral emission function $\Phi(q, v)$ is given by

\[
\Phi(q, v) = \int dx_\alpha \left[ \frac{z}{L} + \frac{1}{2} \right] e^{-i \Delta(q, v) z}. \tag{A5}
\]

Performing the integrals over the spatial coordinates $dx_\alpha$ and $dx_\beta$, one gets

\[
W^{(i)}(q, q', v) = e^{i(2d/k)p_0\left[ |q|^2 - |q'|^2 \right]} \left[ \bar{A}\left[(q - q')\right] \bar{A}\left[- (q - q')\right] + \bar{A}\left[(q + q')\right] \bar{A}\left[- (q + q')\right] \right] \tag{A6}
\]

and

\[
W(q, q', v) = e^{i(2d/k)p_0\left[ |q|^2 - |q'|^2 \right]} \left[ \bar{A}\left[(q + q')\right] \bar{A}\left[- (q + q')\right] + \bar{A}\left[(q - q')\right] \bar{A}\left[- (q - q')\right] \right]. \tag{A7}
\]

Finally, use of the integral representation for the sinc function [Eq. (A5)] allows the $v$ integration to be carried out, but at the expense of introducing two integrations over a pair of new parameters (say, $z$ and $z'$). Note the following relation, which can easily be verified by sketching the functions on the left-hand side:

\[
\Pi[x] \Pi[x - \alpha] = \begin{cases} 
1 & \text{if } -1 \leq \alpha \leq 0, \quad -\frac{1}{2} \leq x \leq \frac{1}{2} + \alpha \\
0 & \text{if } 0 \leq \alpha \leq 1, \quad -\frac{1}{2} + \alpha \leq x \leq \frac{1}{2} \\
0 & \text{otherwise.} 
\end{cases} \tag{A8}
\]

From this, it follows that

\[
\int \Pi[x] \Pi[x - \alpha] dx = \Lambda(\alpha), \tag{A9}
\]

where $\Lambda(\alpha)$ is the triangle function. These facts allow us to carry out the two $\alpha$ integrations that arise from the sinc function, leading to the result shown in Eq. (23).

APPENDIX B: JUSTIFICATION OF EQ. (32)

Suppose we have a set $A$, which can be partitioned into a collection of disjoint subsets $A_k$, with $k=1,2,\ldots$:

\[
\cup_k A_k = A, \quad A_k \cap A_l = \emptyset \quad \text{if} \quad k \neq l. \tag{B1}
\]

To each set we can associate a characteristic function,

\[
\chi_k(x) = \begin{cases} 
1 & \text{if } x \in A_k \\
0 & \text{if } x \not\in A_k 
\end{cases} \tag{B2}
\]

such that

\[
\sum_k \chi_k(x) = \chi_A(x), \quad \chi_k(x) \chi_l(x) = \delta_{kl} \chi_k(x), \tag{B3}
\]

where $\chi_A$ is the characteristic function for the full set,

\[
\chi_A(x) = \begin{cases} 
1 & \text{if } x \in A \\
0 & \text{if } x \not\in A. \tag{B4}
\end{cases}
\]

The term $e^{i\phi_k \chi_k(x)}$ assumes the value of $e^{i\phi_k}$ for $\chi_A(x)=1$ and the value of 1 for $\chi_A(x)=0$ [$1-\chi_A(x)=1$], so
If we express the first few terms we get

\[
\exp \left[ i \sum_k \phi_k \chi_k (x) \right] = \prod_k e^{i \phi_k \chi_k (x)} = \prod_k \{1 - \chi_i (x) + e^{i \phi_i} \chi_i (x)\} = \prod_k [1 + (e^{i \phi_k} - 1) \chi_k] .
\]  

(B5)

If we express the first few terms we get

\[
\prod_k [1 + (e^{i \phi_k} - 1) \chi_k] = [1 + (e^{i \phi_1} - 1) \chi_1][1 + (e^{i \phi_2} - 1) \chi_2] \ldots
\]

\[
= 1 + (e^{i \phi_1} - 1) \chi_1 + (e^{i \phi_2} - 1) \chi_2 + \ldots + (e^{i \phi_1} - 1)(e^{i \phi_2} - 1) \chi_1 \chi_2 + (e^{i \phi_1} - 1)(e^{i \phi_2} - 1)(e^{i \phi_3} - 1) \chi_1 \chi_3 \chi_2
\]

\[
+ \ldots + (e^{i \phi_1} - 1)(e^{i \phi_2} - 1)(e^{i \phi_3} - 1)(e^{i \phi_4} - 1)(e^{i \phi_2} - 1)(e^{i \phi_4} - 1)(e^{i \phi_5} - 1)\chi_1 \chi_2 \chi_3 \chi_4 + \ldots .
\]  

(B6)

So that in the end

\[
\exp \left[ i \sum_k \phi_k \chi_k (x) \right] = 1 + \sum_k [(e^{i \phi_k} - 1) \chi_k] = 1 + \sum_k e^{i \phi_k} \chi_k - \sum_k \chi_k = \sum_k e^{i \phi_k} \chi_k .
\]  

(B7)

Since the square sets we have used in Sec. IV satisfy Eq. (B1), then the result expressed in Eq. (B5) is valid for our case.
