

**Supply Chain Integration:
A Theory Based on Collusion and Communication Costs¹**

Dilip Mookherjee², Alberto Motta³ and Masatoshi Tsumagari⁴

This Version: January 1, 2020

Abstract

We develop a theory of backward integration of a downstream firm owner/HQ whereby it contracts directly with a worker/upstream producer A, instead of delegating this to an informed intermediary S who colludes with A. Non-integration results in higher supply costs owing to intermediary rents, which cannot be eliminated via sophisticated contract design. Integration lowers intermediary rents, but incurs higher costs of communicating and contracting directly with A. The model predictions are consistent with empirical facts concerning circumstances where integration occurs, organization of integrated firms, and effects of integration on workers and aggregate welfare.

KEYWORDS: vertical integration, intermediation, collusion, delegation, double marginalization of rents, foreign direct investment

JEL Classification Nos: D21, D23, D43, L2, F2

1 Introduction

Recent decades have witnessed integration of supply chains in successive waves of ‘corporate re-engineering’ (Hammer and Champy (1993)): downstream firms have integrated backwards in order to contract directly with primary upstream suppliers, often located far away. The main motivation is to reduce supply costs and improve efficiency, by reducing the number of supply chain layers and thereby limit the role of intermediary layers. A critical driver has been advances in information technology (IT) and development of e-platforms allowing such direct contracting. In similar vein, multinational corporations (MNCs) frequently open subsidiaries in foreign countries which contract directly with primary suppliers to produce intermediate inputs, rather than ‘outsourcing’, i.e., procuring these from intermediaries.

In this paper we develop a theoretical analysis of such integration, based on the associated costs of creating new communication links (e.g., e-platforms) needed to contract directly with upstream suppliers. Under non-integration (or outsourcing) the downstream firm owner P contracts with a supply intermediary S , who in turn contracts with a worker or primary supplier A with the requisite skill to produce the input. For concreteness, think of P as a multinational corporation (MNC) located in a Northern country, while S and A are located in a less developed country in the South. P can contract directly with S , and similarly S can contract directly with A . In non-integration, S owns a productive asset that A needs to be able to produce the required input. In addition, S is better informed than P (though less informed than A) about effort that A needs to expend to produce the input.

Integration involves a sale by S to P of the asset that A needs in order to produce. P then incurs the cost of setting up the e-platform or subsidiary needed to contract directly with A . In addition, P might continue to contract with S , to elicit the latter’s information regarding A ’s necessary effort. Under integration, therefore, P contracts both with S and A .

The other main ingredient of the model is collusion between S and A , which allows

them to enter into a (side-)contract with one another which cannot be monitored by any third party.⁵ This is equally true in non-integration and integration. Such collusion is facilitated by the close proximity and past relationship between S and A, and weak institutions (accounting and judicial standards) in the Southern country. This prevents P from monitoring communication or transactions between S and A. Non-integration then inevitably involves double marginalization of rents (DMR), thereby raising rents earned by S and lowering production efficiency. These costs cannot be eliminated by entering into sophisticated contracts, as long as P is unable to contract directly with A.

Integration provides the potential of reducing S's rents and inefficiencies caused by DMR. However, P's efforts to cross-check information reports of S and A in the integrated firm would be undermined by collusion. Our main analytical result is that integration is **less** vulnerable to collusion compared with non-integration. Hence integration lowers supply costs and improves efficiency by reducing the extent of DMR. Integration occurs when this benefit outweighs the fixed cost of direct contracting with A. Our model generates testable predictions regarding the circumstances under which vertical integration arises. These include the role of 'asset specificity', firm-level attributes and contextual attributes such as distance between P and A, and quality of institutions at A's location. Numerical simulations of the model generates insights into welfare and distributional impacts of vertical integration which incorporate spillover effects on welfare of workers, as well as 'pass-through' of external shocks. Section 7 reviews related empirical evidence concerning these predictions.

A standard critique of 'transaction cost' theories of vertical integration is the lack of proper microfoundations for alleged benefits and costs of integration (Gibbons (2005)). DMR, the principal cost of non-integration can be avoided in many models

⁵There are numerous studies in sociology and organizational behavior documenting the role of collusion within organizations; e.g., see the extensive list of citations in Tirole (1986, 1992). These are supplemented by empirical evidence of collusion between management and workers (Bertrand and Mullainathan (1999, 2003), Atanassov and Kim (2009), Cronqvist et al. (2009)).

by sophisticated design of ‘outsourcing’ contracts between P and S. They also lack compelling explanations of intra-firm bureaucratic inefficiencies, low powered incentives or rent-seeking that are believed (e.g., Williamson (1975, 1985)) to constitute the main costs of integration. In our theory, the additional costs of direct contracting consists of the costs of creating a direct contracting link, including channels of direct communication, coordination and payments between P and A. This is in contrast to the standard assumption of zero costs of communication in standard principal-agent models. While it may simplify the analyses of these models, the standard assumption ignores costs of communication systems containing protocols for language, security, transmission and verification of messages sent. Such considerations have given rise to a growing literature on mechanism design with communication costs.⁶ We deliberately abstract from some of the complicating features of models in this literature, by assuming a single production agent and indivisible (0/1) production. This implies that the maximal amount of communication needed is a single binary message from both A and S to P, on which production and payments are conditioned in the integrated firm. Hence the cost of communication can be represented by the fixed cost of creating such a channel.⁷

In the context of supply chain integration, there are detailed accounts of the need for expensive IT-based advances in e-platforms for firms to communicate and contract directly with primary suppliers. For instance, a leading textbook on Supply Chain Integration strategy for small firms lists as one of the principal costs of integration:

“investment in supply chain integration software and compatible information systems throughout the chain” (*Surviving Supply Chain Integration:*

⁶See for instance Green and Laffont (1986, 1987), Melumad, Mookherjee and Reichelstein (1992, 1997), Laffont and Martimort (1998), Blumrosen, Nisan and Segal (2007), Kos (2012, 2014), Blumrosen and Feldman (2013), and Mookherjee and Tsumagari (2014).

⁷With more producing agents and/or continuous production quantities, the design of communication channels includes details such as the size of message spaces, multiple rounds of communication, sequencing of messages etc, which are analyzed in the literature cited above.

Strategies for Small Manufacturers, National Research Council (2000, p.31))

while an *Industry Week* article on supply chain network optimization stated:

“Just imagine how much you could save if you, for instance, increased your capacity utilization by 10%, decreased your inventory by 10%, or reduced your planning cycle time by 40% and the number of planners you employed by 50%. These are common results that our customers are able to achieve. Many supply chain executives are reluctant to invest in supply chain planning and optimization platforms as they are concerned about the cost of these solutions which, of course, are not cheap.” (Balaji and Kumar (Industry Week, July 8, 2013))

In the context of MNCs sourcing inputs from a foreign country, the fixed costs of opening a direct subsidiary includes creation of communication and payment channels with workers and primary suppliers, and acquiring necessary legal and regulatory approvals. These costs are plausibly rising in physical and cultural distance between the two countries, and the weakness of institutions in the Southern country where the subsidiary is located.

Of course, typically bilateral contracts in non-integration also entail costs of setting up communication and payment systems. Our model abstracts from these costs. However it is easy to see that this is an inessential assumption. Integration requires an additional communication link, between P and A — so the fixed cost of integration is just the cost of this additional link. Besides, contracts in integration are more complex, in the sense of containing more contingencies: e.g., the contract between P and S is conditioned not only on messages sent by S, but also those sent by A to P.

At a theoretical level, our model comparing centralization (integration) and decentralization (non-integration) is based on two departures (collusion and communication/contracting costs) from the canonical assumptions underlying the generalized

Revelation Principle (Myerson (1982)). It differs from theories of vertical integration based on incomplete contracts, motivated by problems of unforeseen contingencies, limited commitment or renegotiation. The incentive problem we focus on (private information rents) in a static setting also differs from problems of hold-up in a dynamic setting that form the basis of property rights (PR) based models of vertical integration (Grossman and Hart (1986), Hart and Moore (1990)). Our approach is closer in spirit to recent theories of firm scope of Hart and Holmstrom (2010) that focus on *ex post* inefficiencies arising from *ex post* noncontractibility problems. Our theory differs insofar as asymmetric information and collusion are the source of inefficiency within the integrated firm, rather than *ex post* noncontractibility and conflicting nonpecuniary preferences across stakeholders. A growing literature on MNCs in international economics is based on the PR approach, including both theoretical analyses and empirical testing.⁸ As we elaborate in Section 7, some of our predictions are similar to those of the PR approach, while others are different.

Our model is also related to a large and growing literature on collusion in organizations.⁹ As in our earlier paper (Mookherjee, Motta and Tsumagari (2019)), S and A collude on both reports sent to P, as well as decisions whether to participate in the mechanism offered by P. Laffont and Martimort (1998) is the only other paper we are familiar with that studies the implications of co-existence of collusion and communication costs.¹⁰ Our model differs from theirs in a number of important respects: it

⁸Antras (2013) and Antras and Yeaple (2013) provide excellent surveys of this literature.

⁹See Tirole (1986), Laffont and Tirole (1993), Laffont and Martimort (1997, 2000), Faure-Grimaud, Laffont and Martimort (2003), Mookherjee and Tsumagari (2004), Che and Kim (2006), Celik (2009), and Mookherjee, Motta and Tsumagari (2019).

¹⁰They consider a model of internal organization of a firm involving one principal and complementary tasks involving two production agents who are *ex ante* symmetric but can experience different cost shocks *ex post*. Communication costs constrain the principal in centralization to receive a single dimensional report pertaining to the sum of the costs of the two agents. This restricts the ability of the Principal to treat the two agents asymmetrically *ex post* with resulting incentive losses and inefficiency. These are traded off against problems of double marginalization of rents in a delegation

pertains to integration of two firms rather than internal organization, and the supply intermediary is not involved in production. We also apply the model to the context of the choice of MNCs between outsourcing and foreign direct investment, and discuss related empirical evidence.

The paper is organized as follows. Section 2 provides a self-contained overview of the basic model and main results. Additional model details are presented in Section 3 and results in Section 4. Section 5 provides extensions of the basic model to study effects of higher bargaining power of S in negotiating an acquisition by P; forward integration (where S buys P's firm) as an alternative to backward integration, and alternative forms of collusion between S and A. Section 6 describes welfare implications of integration, using numerical computations of an example with uniformly distributed costs and signals with linear likelihood functions. Section 7 concludes with a summary of the predictions, followed by a comparison of these with predictions of PR-based theories, and a discussion of available empirical evidence related to these predictions.

2 Overview of Model and Main Results

The status quo situation involves two separate firms, one owned by a Principal (P) which corresponds to the Northern MNC, and a Southern firm owned by a supplier S which employs worker A (referred to as the agent). P owns an asset consisting of a technology to produce a product which can be sold on the world market at unit price V_P . The production of this good requires an intermediate input which can only be produced by A using a productive asset and applying some effort. This asset is owned by S. Prior to P's arrival, S and A jointly produce a similar product that can be sold on local Southern markets at price $V_S (< V_P)$. Owing to the absence of other

setting where the Principal contracts with only one of the two agents and delegates the right to subcontract with the other agent.

competitors owning similar assets, the relationship between P and S constitutes a bilateral monopoly. The difference $V_P - V_S$ represents the extent of appropriable quasi-rents or *specificity* in the relationship between P and S.

To simplify the analysis, we assume that the good to be produced for P is indivisible.¹¹ Agent A is privately informed about the effort cost θ of producing the good. S has special expertise regarding production conditions in the South country, represented by a signal η which is partially informative regarding the realization of θ . P does not observe the realization of this signal. Owing to their prior connection, S and A can costlessly communicate and side-contract with one another privately; such communication or transactions are not observed by P or any third party.¹²

With non-integration (NI) where the two firms are separately owned, P and S negotiate an arms-length contract where P buys the good from S, who in turn contracts with A to produce the good. Throughout we assume P has all the bargaining power *vis-a-vis* S, and S has all the bargaining power *vis-a-vis* A.¹³ The key contracting friction between P and S in NI is that P is unable to verify payments made by S to A. This owes to collusion between S and A (whereby S can enter into side-payments with A that cannot be observed by any third party), a problem compounded by poor accounting standards in the Southern country (which allow S to supply P with ‘fake’ invoices for payments to A). This prevents P from entering into cost-sharing contracts with S. Non-integration then results in DMR, owing to a cascading of information rents along the supply chain. Despite the absence of constraints on contracts or mes-

¹¹Most results extend to the context where the quantity produced is divisible. See Mookherjee, Motta and Tsumagari (2019) for details.

¹²Consistent with the literature on collusion in organizations following Tirole (1986), we assume S and A can enter into side contracts that are costlessly enforced (via a third party or on the basis of other parallel relationships between the two of them). The only friction in side-contracting between S and A is the superior information possessed by A regarding the realization of cost θ . Unlike the Tirole (1986) model, there is no ‘hard information’ that restricts reports that can be submitted, so the potential for collusion is considerably more severe in our setting.

¹³In later sections we describe the consequences of alternative distribution of bargaining power.

sage spaces, we show that sophisticated design of contracts with S will not eliminate the DMR problem, as long as P is unable to contract directly with A.

Controlling procurement cost constitutes the prime motive for vertical integration, wherein P acquires the productive asset owned by S that A needs to be productive. This enables P to contract directly with A, upon incurring a fixed setup cost f (which includes the cost of communication/payment infrastructure). In the integrated firm, P seeks to tap S's expertise in order to design a contract for A: hence P invites and cross-matches reports from S and A of their respective private information. This gives rise to incentives for S and A to collude, thereby generating an (endogenous) transaction cost, in addition to the fixed setup cost.

Our first main result is that the gross profit of P in the integrated firm (excluding the fixed set-up cost f) is strictly higher compared to non-integration, under a mild parameter restriction ensuring existence of a DMR problem in the latter. In other words, P is able to reduce the severity of the DMR problem in the integrated firm, despite the presence of collusion. The increase in gross profit is independent of the setup cost f . Hence vertical integration will occur when the set-up cost is smaller than the increase in gross profit achieved; otherwise non-integration will be chosen. The ability to contract directly with A and the setting up of a centralized mechanism with cross-reporting enables a reduction in the DMR problem that was not achievable under non-integration. This is the benefit of integration, which has to be traded off against the setup cost f .

The benefit of integration turns out to depend on the extent of specificity $V_P - V_S$: it approaches zero as specificity approaches zero, and is strictly increasing provided it exceeds some threshold value. The model thus formalizes one of the most important and robust prediction of the transaction cost approach: high specificity renders vertical integration more likely.

The model also generates the following predictions: (i) The integrated firm will benefit from eliciting S's private information regarding worker costs, and setting up

a cross-reporting mechanism; i.e., S will be engaged by the integrated firm as a consultant or manager. (ii) Vertical integration takes the form of backward rather than forward integration: P acquires S's firm rather than vice versa. This contrasts with the PR theory prediction that the owner of the integrated firm will be the party (i.e., S) with the more severe incentive problem. (iii) Vertical integration is more likely to arise if the Southern country has superior communication and legal infrastructure, and when the fixed setup costs of FDI in the South country are lower (e.g. when the distance between the two countries is smaller). (iv) Integration is more likely in industries with higher value products, and for Northern firms that are more productive. As discussed in Section 7, most of these predictions are supported by empirical evidence.

Finally our model yields interesting implications for distributional and welfare impacts of integration. Owing to the difficulty in obtaining explicit analytical solutions, we numerically compute optimal allocations in the integrated firm in an example with uniformly distributed costs. In this example, integration when it occurs results in higher welfare and prices offered to A, in the context involving a bilateral monopoly between P and S.¹⁴ The aggregate rents of S and A (and therefore aggregate surplus, including P's welfare) turn out to be higher under integration. For some parameter values involving low specificity S's rents are unaffected; over this range integration is Pareto improving. The improvement in aggregate efficiency tends to increase in the extent of specificity. For fixed V_S , a larger fraction of increases in V_P are 'passed on' to A (i.e., A's welfare increases by more) under integration, implying greater 'trickle down' effects of globalization benefits to workers. In Section 7 we discuss empirical evidence concerning effects of foreign direct investment by MNCs that confirm these predictions.

¹⁴However, this result may not obtain in an extended version of the model where integration could be accompanied by an increase in monopsony power.

3 Model Details

There are two firms, P and S, and a single worker A. A produces a single unit of the good, and delivers it to either S or P. P earns V_P by selling the good on the world market. S can earn $V_S (< V_P)$ by selling it in the local market; alternatively S can sell it to P. A is privately informed regarding his production cost θ . P and S share a common prior distribution $F(\theta)$ with a positive, differentiable density $f(\theta)$ on support $[\underline{\theta}, \bar{\theta}]$. Not owning a complementary productive asset (owned by S) and/or market reputation, A cannot supply the good to either local or the world market on his own. From past experience, S has accumulated expertise that P does not possess, represented by access to an informative signal η of A's cost. The realization of this signal is observed by S and A jointly. η takes two possible values η_L, η_H . The likelihood of observing signal η_i ($i = L, H$) is $a_i(\theta)$, a positive differentiable function on $(\underline{\theta}, \bar{\theta})$. Let $F_i(\theta) \equiv \frac{1}{\kappa_i} \int_{\underline{\theta}}^{\theta} a_i(y) f(y) dy$ denote the distribution of θ conditional on η_i , where $\kappa_i \equiv \int_{\underline{\theta}}^{\bar{\theta}} a_i(y) f(y) dy \in (0, 1)$ denotes the probability of η_i . The density function of $F_i(\theta)$ is denoted by $f_i(\theta)$.

To ensure the problem is interesting we assume $V_P > V_S > \underline{\theta}$. We also impose standard monotonicity conditions on likelihood ratios and hazard rates:

Assumption 1 (i) $\frac{a_L(\theta)}{a_H(\theta)}$ is decreasing in θ on $[\underline{\theta}, \bar{\theta}]$.

(ii) $H(\theta) \equiv \theta + \frac{F(\theta)}{f(\theta)}$, $h_i(\theta) \equiv \theta + \frac{F_i(\theta)}{f_i(\theta)}$ and $l_i(\theta) \equiv \theta - \frac{1-F_i(\theta)}{f_i(\theta)}$ ($i = L, H$) are increasing in θ .

These can be interpreted in terms of corresponding assumptions regarding supply functions and their elasticity: a low signal corresponds to higher supply (a supply function shifted to the right) and lower price elasticity: $F_H(p) < F(p) < F_L(p)$ and $\sigma_L(p) < \sigma(p) < \sigma_H(p)$ where $F_i(p)$ denotes the likelihood of A supplying the good when offered payment of p , and $\sigma_i(p)$ the elasticity $\frac{p f_i(p)}{F_i(p)}$ conditional on signal η_i , while $F(p)$ and $\sigma(p)$ represent corresponding supply and supply elasticity functions.

A specific example is a uniform prior ($F(\theta) = \theta$ on $[0, 1]$) and linear likelihood function $a_L(\theta) = 1 - \theta$ for $\theta \in [0, 1]$ and $a_H(\theta) = \theta$ for $\theta \in [0, 1]$. See Figure 1.

In the absence of P, S delivers the good to the local market after procuring from A. Following $\eta = \eta_i$, S offers a take-it-or-leave-it price $p_i(V_S)$ to A which maximizes $F_i(p_i)(V_S - p_i)$, and earns an expected payoff $u_i^S \equiv F_i(p_i(V_S))(V_S - p_i(V_S))$.

When P enters, there are two different ways for P to procure the good from the South country:

- Non-Integration (NI): The two firms are separately owned; P procures the good by contracting with S, who becomes a middleman between P and A. In the North-South context, this corresponds to outsourcing.
- Backward Integration (BI): P acquires S's firm, who owns a productive asset that A needs to work with. S transfers this asset to P, enabling P to procure directly from A. In the North-South context, this corresponds to foreign direct investment (FDI) by P via acquisition of a local firm.

In a later section, we shall also consider other alternatives such as forward integration (FI) where S acquires P's firm, procures from A and supplies to the world market. Figure 2 illustrates contract structures in NI, BI and FI.

3.1 Non-Integration

NI features a sequence of bilateral contracts: first P offers a contract to S, then S offers a contract to A. Owing to collusion, it is not possible for P to observe transactions or communication between S and A. Hence P cannot condition the price offer to S on the latter's 'cost', i.e., what S pays A.¹⁵ Moreover, P is unable to prevent S from communicating with A before responding to P's offer.

Formally, the sequence of moves is as follows.

¹⁵Melumad, Mookherjee and Reichelstein (1995) show verifiability of supplier cost is necessary for sequential bilateral contracting to achieve second-best allocations.

0. S observes η , while A observes (θ, η) .
1. P offers S a contract consisting of a message space M_S , quantity $q_S(m_s) : M_S \rightarrow \{0, 1\}$ and payment $X_S(m_s) : M_S \rightarrow \mathfrak{R}$, where M_S includes an exit option e_S and the contract is constrained to satisfy $q_S(e_S) = X_S(e_S) = 0$.
2. S offers A a contract consisting of a message space M_A , quantity $q_A(m_A) : M_A \rightarrow \{0, 1\}$ and payment $X_A(m_A) : M_A \rightarrow \mathfrak{R}$, where M_A includes an exit option e_A and the contract is constrained to satisfy $q_A(e_A) = X_A(e_A) = 0$.
3. A sends a message $m_A \in M_A$ to S.
4. S sends a message $m_S \in M_S$ to P, satisfying $q_S(m_S) \leq q_A(m_A)$.

Proposition 1 *Under Non-Integration, there is a Perfect Bayesian Equilibrium (PBE) resulting in an allocation that can be represented as follows. P delegates production (not deliver/deliver) decisions to S, and offers to pay 0 and b corresponding to non-delivery and delivery of the good respectively. Given any delivery bonus b , in state η_i S offers A a take-it-or-leave-it price $p_i(b) \equiv \arg \max_{p_i \in [\underline{p}, \bar{p}]} F_i(p_i)(b - p_i)$ for $i = L, H$. The good is delivered only if $p_i(b)$ exceeds θ . P selects the bonus b^{NI} which maximizes $[\kappa_L F_L(p_L(b)) + \kappa_H F_H(p_H(b))](V_P - b)$, subject to $b \geq V_S$.*

The proof of this result is straightforward, so we omit the technical details and provide a heuristic account. Sophisticated contracts do not succeed in screening S's private information regarding cost conditions by conditioning trades on messages sent by S, because S can wait to obtain a cost report from A before responding to P's offer. Conditional on the decision on whether the good will be delivered or not (which S knows at the time of responding to P), S can manipulate the report of A's cost to P to maximize the payment promised by P. Hence P's payments to S can only be conditioned on whether the good is delivered.¹⁶

¹⁶See Baliga and Sjostrom (1998) for a similar argument in the context of a model of collusion with moral hazard.

Since the good is indivisible, the ‘outsourcing’ contract between P and S consists of two payments, corresponding to non-delivery (X_0) and delivery ($X_0 + b$) respectively. Payment X_0 in the event of non-delivery must be non-negative, otherwise the coalition of S and A would not accept the offer in that state. This prevents P from using a two-part tariff, where a negative X_0 is used by P to extract S’s rent upfront. The same is true for the ‘subcontract’ offered by S to A: it consists of two payments, corresponding to non-delivery and delivery. To satisfy A’s participation constraints, the payment in the event of non-delivery cannot be negative. It is also evident that it is optimal for S to not pay A anything in the event of non-delivery; hence the subcontract reduces to a single take-it-or-leave-it price offer. Since S receives a bonus of b from P for delivering the good, the optimal price offered by S in state η_i is $p_i(b)$.

Turning now to the contract offered by P to S, note that payment in the event of delivery $X_0 + b$ cannot be smaller than V_S , what S can earn by selling instead to the local market, if S is to be incentivized to accept P’s contract. The contract (b, X_0) generates an expected profit to P of $[\kappa_L F_L(p_L(b)) + \kappa_H F_H(p_H(b))](V_P - b) - X_0$, which is maximized by choosing (b, X_0) subject to $X_0 \geq 0$ and $b + X_0 \geq V_S$, where $p_i(b) \equiv \arg \max_{p_i \in [\underline{\theta}, \bar{\theta}]} F_i(p_i)(b - p_i)$ for $i = L, H$. It is easy to see that the optimal X_0 is zero, and we then obtain Proposition 1.

The solution to NI features double marginalization of rents. A earns rents in contracting with S owing to superior information about θ . These rents account for part of S’s procurement cost. And S is privately informed vis-a-vis P with regard to procurement cost, thereby earning rent on rents paid to A. S’s monopsony power in contracting with A features the standard trade-off between extracting A’s rents and lowering the probability of A’s supply. In setting a price offer for A, S ignores P’s loss of rents when A fails to supply the item, and ends up offering a price to A which is inefficiently low. Alternatively, the supply curve facing P lies above and has a higher slope than the supply curve facing S, since the former additionally includes payments of S’s rents by P. Hence P offers a bonus which is not high enough to elicit

an efficient supply response. See Figure 3 for an illustration of the outcomes in state η_i .

3.2 Backward Integration

In this arrangement, P makes an offer to acquire S's assets, enabling P to organize production and contract directly with A. P would therefore offer to make payments to S in order to acquire these rights. Since information possessed by S about the realization of η would be useful to P in designing a contract for A, it could be additionally beneficial for P to ask S to report this information and condition the payment to S on these reports (besides reports received from A). Of course, A may then have an incentive to bribe S to manipulate the latter's report. Collusion limits the usefulness of P's effort to elicit S's information, as S and A can communicate privately with one another and enter into hidden side-contracts to 'game' the mechanism designed by P. We will later show that it is typically optimal for P to contract with S to elicit the latter's information in the integrated firm. Hence we need to consider the implications of P contracting with both S and A in the integrated firm.

Since S and A already know one another before P arrives, collusion between S and A occurs *ex ante*, where they negotiate a side-contract prior to responding to P's offer.¹⁷ We make the standard assumption in the literature on collusion (following Tirole (1986)) that the side-contract between S and A is costlessly enforceable by some third party. Following private communication of a cost message by A to S, the side-contract coordinates their respective messages (which include participation decisions and cost reports) sent to P, besides a side payment between A and S. Unlike Tirole (1986), information is 'soft', i.e., message spaces are unrestricted, with both S

¹⁷This is in contrast to *interim* collusion where S is required to communicate his participation decision to P before communicating with A, as in the analyses of Faure-Grimaud, Laffont and Martimort (2003) or Celik (2009). The implications of this contrast are elaborated in detail in Mookherjee, Motta and Tsumagari (2019).

and A able to send ‘false’ messages. S offers a side contract to A, which A accepts or refuses.

In the event of A refusing this side-contract, they play P’s mechanism non-cooperatively. Unlike NI, A receives a contract directly from P, which can now be conditioned on reports sent by S regarding the realization of η . As elaborated in Mookherjee, Motta and Tsumagari (2019) in the context of a more general version of this model, this allows P to manipulate the outside options of A in bargaining over a side contract, reducing the severity of the DMR problem. Raising A’s outside option forces S to offer a higher price to A for delivering the good, thereby alleviating the underproduction in NI.

We explain how the logic plays out in this setting. The specific context here (i.e., an indivisible good being procured and two-point cost signals received by S) allows considerable simplification of the analysis of optimal mechanisms in BI. It can be shown that P loses nothing by confining attention to revelation mechanisms (in which message spaces are type spaces) that are (i) individually incentive compatible, i.e., S and A accept and report their types truthfully, and (ii) collusion-proof, which leave no room for S and A to enter into a non-null side contract.¹⁸ Hence P can confine attention to mechanisms satisfying a set of individual and coalition incentive compatibility constraints.

In order to describe the mechanism design problem in BI, it is necessary to be explicit about the exact sequence of events by which P negotiates the acquisition of S’s firm (depicted in Figure 4):

(BI-i) P offers S the following proposal, which is hereafter referred to as the BI mechanism. It specifies message spaces M_A, M_S for A and S respectively, production decision $q(m_A, m_S)$ and transfers $X_A(m_A, m_S), X_S(m_A, m_S)$ conditioned on submitted messages. A’s message space includes an exit option which is followed by absence of production and transfers to A. S has the opportunity to reject

¹⁸See the online Appendix of Mookherjee, Motta and Tsumagari (2019) for the detailed argument.

P's offer after communicating with A, so an additional exit option for S does not need to be included in M_S .

(BI-ii) S proposes a side-contract to A describing how they can jointly respond to P's offer. The side-contract (SC) specifies a private report of the true cost θ from A to S, followed by joint messages $m(\theta, \eta) \in M_A \times M_S \cup \{Exit\}$ they respectively send to P, a private side-payment $t(\theta, \eta)$ from S to A, and production supplied to the local market $q(\theta, \eta) \in \{0, 1\}$ for (θ, η) in the event that they decide to reject P's mechanism ($m(\theta, \eta) = Exit$). The set of side contracts includes the Null Side Contract (NSC), where S proposes no side contract at all, or equivalently that they play the rest of the game noncooperatively (as explained in more detail in (BI-iv) below).

(BI-iii) A responds by rejecting or accepting SC (while NSC is automatically accepted). If SC is accepted, it is implemented and the game ends.

(BI-iv) If S had offered a non-null SC and A rejects it, or if S had offered NSC, S and A play non-cooperatively thereafter. This consists of the following stages. (a) S decides whether to accept P's offer. (b) If S does accept it, P sets up the integrated firm, and S and A play the BI mechanism noncooperatively. If S rejects P's offer, S offers a contract to A to deliver the product to the local market.

The solution concept employed is Perfect Bayesian Equilibrium (PBE) which is Pareto-undominated for the $\{S, A\}$ coalition, i.e., for any η , there does not exist any other PBE which improves S's payoff, without making any type of A worse off.¹⁹

We now characterize properties of allocations that can be achieved as outcomes of PBE satisfying this criterion. To simplify the exposition we focus on equilibria in which BI is accepted by S in both states η_L, η_H . Proposition 3 below shows that

¹⁹This refinement is essential to capture the prospect of collusion between S and A, as explained in Mookherjee, Motta and Tsumagari (2019).

such equilibria also generate higher profit for P than any equilibrium in which BI is accepted by S in only one of the two states.

Since the good is indivisible and the mechanism has to be individually incentive compatible and collusion-proof, abstract message spaces can be dispensed with and the allocation can be represented more simply by a set of prices that satisfy a set of constraints described below. We eschew the technical details and provide an intuitive account.

First, a contract offered by P to A in the BI mechanism reduces to a single take-it-or-leave-it price offer p_i made to A when the cost signal is η_i . Second, in order to deter collusion, P must offer an aggregate payment to S and A which depends only on whether or not the good is produced. Let $X_0 + b, X_0$ denote the aggregate payments when the good is and is not produced respectively. The two prices p_L, p_H combined with (b, X_0) characterize a BI allocation entirely. This is associated with a mechanism where S and A are asked to submit reports $(\hat{\eta}_S, \hat{\eta}_A)$ of the signal η to P. If the two reports happen to match ($\hat{\eta}_S = \hat{\eta}_A = \eta_i$), A is offered the option to produce and deliver the good directly to P in exchange for price p_i , while S is paid X_0 if the good is not delivered, and $b + X_0 - p_i$ if it is delivered. If the two reports do not match, there is no production and S and A are required to pay a high penalty to P. The key feature distinguishing BI from NI allocations is that in the former P makes a contract offer directly to A which is conditioned on reported signals. This provides an outside option to A which S is constrained to match while offering a side contract to A. This is an important strategic tool that enables P to manipulate the outcome of collusion between S and A, and reduce the severity of the DMR problem.

Along the equilibrium path (where A and S decide to participate, report η_i truthfully to P, and do not enter into a deviating side-contract), A produces the good in state η_i and receives the payment p_i if and only if θ_i is smaller than p_i . Without loss of generality, A receives no payment in the event of non-production.²⁰ This generates

²⁰It can be checked that any mechanism paying a positive amount to A in the event of non-

utility to A of $u_A(\theta, \eta_i) = \max\{p_i - \theta, 0\}$. S ends up with $X_0 + b - p_i$ in the event that production takes place, and X_0 otherwise.

The BI allocation (p_L, p_H, b, X_0) must satisfy the following constraints. First, in order to ensure that *ex post* the coalition does not prefer to reject it or supply to the local market instead:

$$b + X_0 \geq V_S \quad (1)$$

$$X_0 \geq 0. \quad (2)$$

Second, in order to induce S to agree to participate in GC, S's interim expected utility cannot fall below what he could earn by supplying to the local market instead:

$$F_H(p_H)(b - p_H) + X_0 \geq u_H^S \quad (3)$$

$$F_L(p_L)(b - p_L) + X_0 \geq u_L^S. \quad (4)$$

Third, S and A should not be tempted to enter a deviating SC. A deviating SC would involve a different set of prices \tilde{p}_i offered to A (in state η_i) for delivering the good, combined with a lump-sum payment \tilde{u}_i . A would then produce if θ is smaller than \tilde{p}_i , and S would earn an expected payoff $F_i(\tilde{p}_i)(b - \tilde{p}_i) + X_0 - \tilde{u}_i$. A would accept the deviating SC provided

$$\max\{\tilde{p}_i - \theta, 0\} + \tilde{u}_i \geq \max\{p_i - \theta, 0\} \quad (5)$$

Hence collusion-proofness requires $(\tilde{p}_i, \tilde{u}_i) = (p_i, 0)$ to maximize $F_i(\tilde{p}_i)(b - \tilde{p}_i) + X_0 - \tilde{u}_i$ subject to (5).

This condition can be broken down as follows. First, if $p_i > \underline{\theta}$, S should not benefit by deviating to a price $\tilde{p}_i < p_i$. This would necessitate offering a lumpsum payment of $\tilde{u}_i = p_i - \tilde{p}_i$ to ensure that A accepts the SC, which would then generate S an interim expected payoff of $F_i(\tilde{p}_i)(b - \tilde{p}_i) + X_0 - p_i + \tilde{p}_i$. This is equivalent to requiring that

$$b \geq p_i - \frac{1 - F_i(p_i)}{f_i(p_i)} \equiv l_i(p_i) \quad (6)$$

production is dominated by one that does not.

since $l_i(p)$ is increasing in p as per the monotone hazard rate assumption (Assumption 1(ii)). Intuitively, offering a lower price than p_i is similar to S selling the good back to A. Condition (6) which states that the value b of the good to S exceeds its virtual value to A ensures that such a sale is not worthwhile.

Similarly, if $p_i < \bar{\theta}$, S should not want to offer A a higher price \tilde{p}_i . Unlike the case of a lower offer price, such a variation cannot be accompanied by a negative lump sum payment \tilde{u}_i to A, owing to the need for A's ex post participation constraint to be satisfied in non-delivery states. Offering $\tilde{p}_i > p_i$ will then generate an interim payoff of $F_i(\tilde{p}_i)(b - \tilde{p}_i) + X_0$. For S to not want to deviate to a higher price, it must be the case that

$$b \leq p_i + \frac{F_i(p_i)}{f_i(p_i)} = h_i(p_i) \quad (7)$$

given the monotone hazard rate assumption. This condition can be interpreted simply as the value of delivery (b) to S being lower than the virtual cost of A of delivering it.

(6, 7) can be combined into the single collusion-proofness condition

$$\max\{\hat{l}_L(p_L), \hat{l}_H(p_H)\} \leq b \leq \min\{\hat{h}_L(p_L), \hat{h}_H(p_H)\}. \quad (8)$$

where $\hat{h}_i(p)$ denotes $h_i(p)$ for $p \neq \bar{\theta}$ and ∞ otherwise, and likewise $\hat{l}_i(p)$ denotes $l_i(p)$ for $p \neq \underline{\theta}$ and $-\infty$ otherwise.

The preceding arguments explain the necessity of conditions (1, 2, 3, 4, 8) for an allocation (p_L, p_H, b, X_0) to be feasible in BI. They are also sufficient: in the Appendix we show that a coalition-Pareto-undominated PBE can be constructed which results in this allocation.

Lemma 1 *A BI allocation (p_L, p_H, b, X_0) is feasible, i.e., incentive compatible and collusion-proof, if and only if it satisfies conditions (1, 2, 3, 4, 8).*

Finally, an optimal BI allocation must maximize

$$[\kappa_H F_H(p_H) + \kappa_L F_L(p_L)](V_P - b) - X_0 \quad (9)$$

subject to (1, 2, 3, 4, 8). We shall denote the solution by $(p_H^{BI}, p_L^{BI}, b^{BI}, X_0^{BI})$, and the accompanying expected profit of P by Π^{BI} , gross of the fixed setup cost f that the BI mechanism entails. We shall hereafter refer to Π^{BI} as the operating profit of P in BI, which excludes the setup cost f , so that the net profit equals $\Pi^{BI} - f$. This needs to be compared with Π^{NI} when P decides whether or not to acquire S's firm. An acquisition will occur only if BI earns a higher operating profit by enough to cover the setup cost: $\Pi^{BI} - \Pi^{NI} > f$.

It is evident that at least one of either (1), (3) and (4) must be binding in the optimal allocation.²¹ It is also evident that P's maximal profit Π^{BI} approaches zero as the extent of specificity $V_P - V_S$ approaches zero.²² Hence it is necessary there be a non-negligible degree of specificity for BI to be chosen rather than NI.

4 Main Results

4.1 Comparing Non-Integration with Backward Integration

We now compare P's operating profits in NI and BI. Note first that P can always attain in BI at least the profits achieved in NI, since the latter is equivalent to unconditionally delegating authority to S to contract with A within BI (i.e., where P does not offer a contract to A, so A has no outside option in bargaining with S over the side contract).²³ The question is whether P can achieve *strictly* higher profit in BI by enough to overcome its setup cost to be worthwhile.

This cannot happen when V_S is large enough relative to the upper bound $\bar{\theta}$ (specif-

²¹Otherwise $X_0 = 0$ and $b = \max\{\hat{l}_L(p_L), \hat{l}_H(p_H)\}$. Then $b < p_i$ for each i , and S's participation constraint will be violated.

²²(1) implies aggregate payments $b + X_0$ to the coalition in the event of the good being delivered approaches what P can sell the good for, so P's profit in this event approaches zero. And (2) ensures that P cannot make any profit if the good is not delivered.

²³Specifically, the optimal NI allocation corresponds to a BI allocation with $p_i = p_i^{NI}, b = b^{NI}, X_0 = 0$.

ically, if $V_S \geq h_L(\bar{\theta})$) that P always procures the good in NI, by offering a price large enough to guarantee that the good is delivered ($p_L^{NI} = p_H^{NI} = \bar{\theta}$).²⁴ In that case NI involves no underproduction and hence is not subject to any DMR problem: there cannot be any scope for achieving higher operating profit by acquiring S's firm.

Our first main result is that in all other cases, BI does attain a higher operating profit.

Proposition 2 $\Pi^{BI} > \Pi^{NI}$ if and only if $h_L(\bar{\theta}) > V_S$.

Proposition 2 implies that whenever NI involves a price below the maximum cost $\bar{\theta}$ and is thereby potentially subject to a DMR problem, BI will be preferred if f is small enough, and NI will be preferred otherwise. The reasoning underlying this result is illustrated in Figure 5. Suppose that the price offered to A in NI in state L is smaller than $\bar{\theta}$, so there is scope for raising the price further in this state. Let P select $p_L = p'_L$ in BI which is slightly higher than p_L^{NI} , while leaving the price in state H and S's delivery bonus b unchanged ($p_H = p_H^{NI}, b = b^{NI}$). This raises the probability of the good being delivered, resulting in a first-order increase $[F_L(p'_L) - F_L(p_L^{NI})](V_P - b^{NI})$ in P's expected profit. On the other hand, S's payoff in L falls since p_L^{NI} had been optimally chosen by S in NI given the delivery bonus b^{NI} which remains unchanged. To compensate S for this, P needs to offer a positive lump-sum payment $X_0 = F_L(p_L^{NI})(b^{NI} - p_L^{NI}) - F_L(p'_L)(b^{NI} - p'_L)$. But S's loss is second-order, so the cost of this compensation is smaller than the gain in P's profit owing to the higher probability of delivery. As the resulting allocation is feasible in BI, i.e., satisfies conditions (1, 2, 3, 4, 8), it follows that P earns a higher operating profit in BI.²⁵ Contracting directly with A allows the DMR problem to be reduced, as P offers a higher price to A which S is forced to match in BI.

²⁴Recall that $b^{NI} \geq V_S$ is necessary to satisfy S's participation constraint in NI. Hence $V_S \geq h_L(\bar{\theta})$ implies $b^{NI} \geq h_L(\bar{\theta})$. Then $p_L^{NI} = \bar{\theta}$.

²⁵Condition (8) holds since $b^{NI} = h_L(p_L^{NI}) > l_L(p_L^{NI})$, so p'_L slightly higher than p_L^{NI} implies $h_L(p'_L) > b^{NI} > l_L(p'_L)$. It is evident that the other conditions also hold.

Corollary 1 (i) If $h_L(\bar{\theta}) > V_S$, and given specificity $V_P - V_S$, P prefers BI to NI if fixed cost f of BI is sufficiently small.

(ii) Higher specificity enlarges the range of fixed costs for which P prefers BI, over a range of high levels of specificity (i.e., when V_S is small relative to V_P).

(iii) Given any f , if specificity is sufficiently low, P prefers NI to BI.

(i) is evident, while (ii) follows from the following argument. For fixed V_P consider the implications of varying the degree of specificity, i.e., letting V_S vary over the range $[0, V_P)$. When specificity is high (i.e., V_S is low), the solution to NI is locally independent of V_S as S 's participation constraint is not binding. On the other hand, some participation constraint is always binding in BI, and a fall in V_S relaxes these constraints, so P 's profit in BI increases as a result. Hence integration becomes more attractive with higher specificity. Over low ranges of specificity, optimal profits in both NI and BI are decreasing in V_S , and it is difficult to compare the rates at which they respectively fall. See however the numerical examples in Section 6 where benefits of integration are everywhere increasing in specificity. Finally, result (iii) follows from the fact that P 's profits approach zero under either NI and BI when specificity approaches zero.

The next Proposition provides a rationale for focusing on equilibria where BI results in both states η_L, η_H . It shows that such equilibria generate higher profits for P compared with those in which BI results in only one state η_i , while in the other state $\eta_j, j \neq i$ S refuses to sell the firm to P , with either NI resulting in that state, or S does not sell to P at all and sells to the local market instead. The argument is essentially similar to that used in Proposition 2 above: reductions in DMR resulting from integration generate benefits to P in each and every state separately, though the argument is complicated by the feature that the feasibility constraints pertain jointly to both states.²⁶

²⁶The Proposition compares operating profits. Under the assumption that the BI setup costs are

Proposition 3 (a) *Any equilibrium in which BI results in only one state η_i , while in the other state $\eta_j, j \neq i$ there is no trade between P and S (i.e., S supplies to the local market) generates less operating profit for P than an equilibrium in which BI results in both states.*

(b) *Suppose $V_P < h_H(\bar{\theta})$. Then any equilibrium in which BI results in one state, and NI in the other, generates less operating profit for P than an equilibrium in which BI results in both states.*

4.2 Value of Eliciting S's Information in Integrated Firm

In BI, the potential advantage of P contracting with S is that the information reported by S helps P reduce A's rents. On the other hand, S will earn some rents owing to collusion, which cannot be taxed away upfront by P (owing to the *ex ante* nature of the collusion). Is it then beneficial for P to hire S as a supervisor? Above we restricted attention to a particular form of BI in which P contracted with S to provide a cost signal report which is used by P to contract with A. We now consider whether P would be better off not trying to elicit S's information. In that case S must sell his firm to P in exchange for a lumpsum amount X_0 in both states η_L, η_H , S does not send any report of the signal η , and P's payment to S does not depend on the output produced by A (i.e., $b = 0$). After acquiring S's firm, P contracts with A on the basis of his prior beliefs over θ .

Let the mechanism be denoted by NS. P will directly offer A a price p (which does not depend on η), and offer S a lumpsum X_0 for acquiring the firm. These will be selected to maximize

$$\max F(p)(V_P - p) - X_0$$

incurred prior to P making the GC offer, it implies that the net profits of the allocation where BI results in both states is higher than when it results in only one state.

subject to

$$X_0 \geq \max\{u_H^S, u_L^S\}$$

$$X_0 + p \geq V_S.$$

The first constraint is required to ensure S is willing to sell the firm in both states η_L, η_H . Since $u_L^S \geq u_H^S$ by Assumption 1(i), it reduces to $X_0 \geq u_L^S$. The second constraint prevents coalitional exit from the grand contract. Let (p^{NS}, X_0^{NS}) denote the solution to this problem, and Π^{NS} be the associated profit.

Proposition 4 *Assume that $H(\bar{\theta}) > V_P > V_S > \underline{\theta}$. Then $\Pi^{BI} > \Pi^{NS}$.*

The reasoning is as follows. Without learning S's signal, it is optimal for P to offer an interior price $p^{NS} < \bar{\theta}$ to A, since $H(\bar{\theta}) > V_P$. The acquisition price X_0 paid to S is at least u_S^L which is strictly greater than u_S^H , since $V_S > \underline{\theta}$. Hence S's participation constraint is slack in state H . Eliciting S's information enables P to raise p_H slightly above p^{NS} , while selecting $b = p_L = p^{NS}$ and leaving X_0 unchanged. Owing to positive slack in S's participation constraint in state H , this allocation is feasible in BI, and generates higher profit for P.

The result continues to hold when NS involves a sale of S's firm in only one state, but not the other. Here P can learn the state from observing whether S accepts the BI offer. The case where S sells the firm in one state η_i but is not engaged is a special case of an allocation where BI results only in state η_i in which the payment to S is independent of what A produces ($b = 0$). Proposition 3 shows P can earn higher profit from an allocation where BI results with S engaged in both states.²⁷

²⁷Note that the conclusion relies on the assumption that NS and BI both involve the same fixed setup cost, which is reasonable since these setup costs pertain to the incremental (relative to NI) costs incurred by P of contracting and communicating with A.

5 Variations and Extensions

5.1 Better Institutions in the South

What are the consequences of better institutions? The answer depends on the precise nature of the improvement. If the key problem with NI is poor accounting standards in the Southern country (rather than collusion), there will be an improvement if S's payments to A can be verified by P. In that case, sophisticated cost-based contracts can overcome the DMR problem, leaving no scope for integration to increase P's profits.

Proposition 5 *Suppose that $V_P < h_L(\bar{\theta})$. If P can verify side-payments between A and S, second-best profits ($\equiv \sum_i \kappa_i [F_i(p_i(V_P))(V_P - p_i(V_P)) - u_i^S]$) can be achieved in NI.*

The argument (provided in the Appendix) is that with verifiable costs P can effectively mandate what price p_i S must pay A for delivering the output following a cost report of η_i made by S to P. Corresponding payments $X_i, X_i + b_i$ from P to S in the event of output being not delivered and delivered can also be stipulated in the NI contract. The only room for S to behave strategically is to misrepresent the true cost signal to P. This turns out to not be a problem: under the same condition as in Proposition 2, P has enough instruments to induce S to report truthfully while implementing the second-best allocation in NI. Note in particular that with cost verifiability, collusion between S and A has no bite in NI.

Suppose on the other hand that accounting standards are poor (resulting in non-verifiability of costs of separately owned firms), and improved institutions consist of reduced prospects for collusion between S and A. For instance, side contracts can no longer be enforced or involve considerable enforcement costs that generate deadweight losses in side-contracts. Then NI continues to be plagued by DMR, while BI achieves higher profits owing to lower collusion costs. In this case, improved institutions make

vertical integration more likely. Hence the impact of better institutions overall are ambiguous, and can go either way.

5.2 Varying Bargaining Power between P and S

So far we assumed P has all the bargaining power in negotiating the acquisition with S. What happens if S also has some bargaining power? Suppose, for instance, that after P has decided to try to acquire S's firm and has incurred the setup cost f , a third-party assigning welfare weight $\alpha \in [0, 1]$ to S designs the grand contract instead of P.²⁸ If P decides to go the outsourcing route instead, the NI contract is designed by the same third-party with the same welfare weight α assigned to S.

If $\alpha > \frac{1}{2}$, S is assigned greater bargaining power than P. In this case, the optimal mechanisms in both NI and BI award zero rent to P, whence the DMR problem disappears and both NI and BI can attain second-best allocations. Hence shifting bargaining power in favor of S makes BI less likely. This is the consequence of the assumption that in the bargaining between P and S, there is one-sided asymmetric information; whence raising the bargaining power of the informed party reduces the inefficiency underlying DMR. If asymmetric information were bilateral (e.g., if P were privately informed regarding the realization of V_P), the result would depend on the allocation of bargaining power *vis-a-vis* private information.

5.3 Forward Integration

Consider an alternative form of integration, where S acquires P's firm and thus the right to sell the product in the world market at price V_P . Call this FI. The game corresponding to P's offering FI instead of BI is as follows.

The grand contract offered by P consists of a 'price' Q at which P is willing to sell her firm to S. It is easy to check that there is no value from basing this on a message

²⁸A participation constraint for P has to be added, to ensure that P earns non-negative expected profit.

submitted by S, for the same reason that there is no value from basing the outsourcing price in NI on messages sent by S (i.e., that S can respond to P's offer after consulting A). If S accepts the offer, it thereafter operates the integrated firm FI, hiring A to produce the product which is sold abroad at price V_P . S then ends up earning a net price of $V_P - Q$ for selling abroad, after subtracting the cost of purchasing the firm from P. This is equivalent to the NI alternative we have already considered where P offers an outsourcing price of $b = V_P - Q$. Hence if $\Pi^{BI} - f > \Pi^{NI}$, P will prefer to acquire S rather than sell his own firm to S.

This shows one prediction of our model which differs sharply from PR-theories of ownership: ownership of the integrated firm should rest with the party with the 'less severe' incentive problem.

6 Incentive and Welfare Implications of Integration

In this section we address questions pertaining to production, incentive and welfare implications of vertical integration, using non-integration as a benchmark. Owing to the complexity of the mechanism design problem within BI, we are unable to derive analytical results concerning these questions. However, optimal BI and NI allocations can be numerically computed in specific examples. Here we consider the case where $V_P = 1$, θ is uniformly distributed on $[0, 1]$, signal probabilities $\kappa_H = \kappa_L = 1/2$, and the distributions of θ conditional on signal realizations are given by $F_L(\theta) = 2\theta - \theta^2$, $F_H(\theta) = \theta^2$ (which correspond to linear likelihood functions $a_L(\theta) = 1 - \theta$ for $\theta \in [0, 1]$ and $a_H(\theta) = \theta$ for $\theta \in [0, 1]$ of the signal conditional on θ).

Figure 6 plots operating profits of P under BI and NI respectively, as V_S (and hence degree of specificity) is varied over the range $[0, V_P] = [0, 1]$. It shows Π^{BI} and $\Pi^{BI} - \Pi^{NI}$ are both decreasing in V_S , while Π^{NI} is decreasing over a range of high V_S where S's participation constraint binds and is constant for lower values of V_S where

it does not.

The likelihood of procurement in either regime depends on the prices offered to A. We expect that BI will feature higher prices owing to a reduction in DMR. This is confirmed in Figure 7.

It is often argued that intra-firm contracts feature low-powered incentives compared to market relationships. The comparison of prices offered to A indicates that the integrated firm offers higher incentives to production level workers at the bottom of the organization. On the other hand, the incentive component in the aggregate payments to S and A, given by the bonus b , behaves differently. Figure 8 shows that BI features a lower bonus than NI for high levels of specificity, and the same bonus for low specificity. At the same time BI features a positive base payment X_0 when the integrated firm produces nothing, at high levels of specificity. BI therefore involves a reallocation of incentive payments between A and S: increasing them for bottom layer members while lowering them for ‘managers’ at intermediate layers, with the latter effect dominating.

Consider next the welfare impacts of BI. Figure 9 plots expected payoffs of A and S respectively. It is evident that production workers welfare increases, owing to the higher prices (i.e., efficiency wages) offered to them. For high specificity (low V_S) S is worse off under BI, while for lower specificity S’s payoff is unaffected (owing to a binding participation constraint over this range). Hence BI redistributes welfare from S to A when specificity is high. Figure 10 shows a higher impact on welfare in the Southern country, measured by the sum of A and S’s payoffs. As P is better off with BI whenever it occurs, this is reinforced when we consider world welfare, the sum of P, S and A’s payoffs. The black line in Figure 11 plots world welfare, corresponding to fixed cost set at $f = 0.05$. It shows that BI occurs only when specificity is large: when V_S is smaller than 0.55. The integration decision involves an externality: P makes the decision based on consequences of P’s own profit, disregarding the benefits accruing to the South country. Hence there is a discontinuous downward drop in world welfare

at $V_S = 0.55$: as V_S rises slightly above the threshold, P decides not to integrate. Over a range of values of V_S slightly above 0.55, there is too ‘little’ integration owing to this externality. However, for V_S close enough to $V_P = 1$ non-integration is welfare optimal and this externality ceases to be relevant.

Figure 12 examines ‘pass-through’ of increases in V_P to A and S’s payoffs, by fixing $V_S = 0.2$ and varying V_P over the range $[0.2, 1]$. We see higher pass-through to A and lower pass-through to S in BI. Hence a larger fraction of benefits of increases in export prices are passed on to workers, and less to intermediaries under integration.

These results concerning benign effects of FDI on worker welfare are however sensitive to our assumption concerning market concentration. So far we have considered a bilateral monopoly between P and S; in such a context BI replaces the monopsony of the local employer S (in contracting with A) by that of the foreign employer P. Concerns about possible adverse impacts of FDI on worker welfare are often based on the possibility that it may increase employer market power. It is possible to extend our model to incorporate multiple competing suppliers, which show this possibility.²⁹

Finally, many empirical studies of FDI have shown that it is more likely to happen in industries with more R&D intensive and higher quality products involving higher export values as well as production costs. Such products would involve higher values of V_P and V_S , as well as cost θ . The effect of scaling up V_P, V_S, θ uniformly will make BI more likely, since this is equivalent to scaling down the setup cost f for fixed V_P, V_S, θ .

7 Conclusion: Summary of Predictions, Related Literature and Empirical Evidence

Our model yields the following predictions: vertical integration is more likely to be observed when (a) specificity is high; (b) fixed costs of setting up an integrated firm

²⁹This was included in a previous version of this paper, and is available on request.

in the Southern country are low, owing to fewer regulations, superior communication and information technology, and closer proximity between the two countries; and (c) in higher value industries and products. (d) The effects of better institutions depend on the precise source of improvement: improved accounting standards *per se* lower the value of integration, while lower collusion prospects within firms raise the value of integration.

Other predictions pertain to the nature of integrated firms, and their welfare effects. (e) Intermediaries whose firms are acquired will be engaged as consultants or managers in the integrated firm. Delegation of authority to such managers is limited, in order to ensure better treatment of workers compared with non-integration. (f) Worker welfare, wages and productivity will be higher in integrated firms. (g) Intermediaries will be worse off, if specificity is high enough. In such instances they will lobby Southern country governments to prevent FDI deregulation, though aggregate Southern welfare will be higher with FDIs. (h) Integrated firms will pass on a larger share of increased firm revenues to workers when consumers are willing to pay more for the product. (i) Backward rather than forward integration occurs when the Southern country supplier rather than the Northern firm is subject to incentive problems.

The empirical literature on multinational firms provides evidence consistent with predictions (a), (b) and (c), which also coincide with predictions made by PR-based theories. Many studies have confirmed that the share of intra-firm trade in total trade is positively correlated with capital intensity, R&D intensity and skill intensity both across industries and across firms.³⁰ More productive firms are more likely to engage in FDI rather than outsourcing (Tomiura (2007)). Greater distance (both physical and cultural) between countries makes FDI less likely (Gorodnichenko et al. (2015)), while enhanced information and communication technology raise intra-firm trade shares (Chen and Kamal (2016), Cristea (2015)).

³⁰See Antras (2013), Antras and Yeaple (2013), Nunn and Treffer (2013), Corcos et al. (2013).

Regarding effects of better institutions in the South, no study that we are aware of distinguishes between effects of improved accounting standards and reduced collusion. Some studies (e.g., Corcos et al. (2013)) show a positive correlation of FDI with governance and contract enforcement institutions in the host country. Other studies show ambiguous results: e.g., Bernard et al. (2010) find that while increased governance quality raises the probability that foreign affiliates are present, it also lowers intra-firm trade shares conditional on existence of a foreign affiliate. This is consistent with our model if fixed costs of integration are lower when governance quality is better.

Standard PR-based theories do not make any particular predictions analogous to (e)–(h) concerning internal organization of integrated firms, spillover welfare effects or pass-through of firm revenues to workers or customers. A number of empirical papers provide evidence consistent with our predictions. Neiman (2010) and Hellerstein and Villas-Boas (2010) show in specific US industries that integrated firms pass on effects of exchange rate or other external shocks at a significant rate to customers; they explain this result by lower incidence of DMR. Alfaro-Urena, Manelici and Vasquez (2019) find MNCs pay workers in Costa Rica a 9% wage premium relative to domestic employers. Conyon et al. (1999) show that acquisitions by foreign firms raised worker wages significantly while those acquired by domestic owners lowered wages, after controlling for firm, industry and year dummies in a sample of 600 British firms. Similar wage effects of FDI are reported by Lipsey (2004). Studies of FDI effects on farming sector in various African, Asian and East European countries generally show positive effects on farmers and small suppliers (Dries and Swinnen (2004), Minten et al. (2009), Maertens et al. (2011), Rao and Qaim (2011) and Michelson et al. (2013)).

Finally, concerning prediction (i) regarding backward versus forward integration, which differentiates our theory from the PR-approach, casual empiricism suggests that backward integration by Northern MNCs is more common. However, we are not

aware of any careful evidence on this issue. Our model therefore suggests the need for further empirical work testing predictions (e)-(i).

Appendix: Proofs

Proof of Lemma 1: For an arbitrary allocation which satisfies (1, 2, 3, 4, 8), construct the following grand contract. If A and S report the same $\eta = \eta_i$ to P, S receives $b + X_0 - p_i$ and A receives p_i when A delivers the good, while S receives X_0 and A receives 0 when A does not deliver. If they submit different reports, they are punished with large negative transfers.

Given this grand contract, there exists a PBE in which S offers a null side-contract to A. Along the equilibrium path, S and A play P's mechanism non-cooperatively, participate in the mechanism and report η_i truthfully. A produces the good if and only if $\theta \leq p_i$. If S offers a non-null SC, attention can be confined to SC's which A always accepts and behaves in an incentive compatible fashion. The stated conditions ensure that there is a PBE where S offers a null side contract, and there does not exist any alternative PBE which is interim Pareto superior for the coalition.

Proof of Proposition 2: If $p_L^{NI} < \bar{\theta}$, the argument described in the text shows that $\Pi^{BI} > \Pi^{NI}$. So suppose that $p_L^{NI} = \bar{\theta}$. Since $p_L^{NI} \leq p_H^{NI}$ (owing to $h_L(\theta) > h_H(\theta)$ on $(\underline{\theta}, \bar{\theta}]$ by Assumption 1(i)), we have $p_L^{NI} = p_H^{NI} = \bar{\theta}$. This implies that $b^{NI} \geq h_L(\bar{\theta}) > h_H(\bar{\theta})$.

First consider the case that $h_L(\bar{\theta}) > V_S$. Then P would never want to raise b^{NI} above $h_L(\bar{\theta})$ as this is an upper bound to the cost incurred by S in ensuring that the good is delivered. Hence we have $b^{NI} = h_L(\bar{\theta})$ and P attains a profit of $\Pi^{NI} = V_P - h_L(\bar{\theta})$. On the other hand, P can select the following allocation in BI: $(p_L, p_H, b, X_0) = (\bar{\theta}, \bar{\theta}, h_L(\bar{\theta}) - \epsilon, 0)$. For sufficiently small $\epsilon > 0$, this satisfies all constraints of the problem in BI and P earns a profit of $V_P - b^{NI} + \epsilon$, which is higher than Π^{NI} .

Next consider the case that $h_L(\bar{\theta}) \leq V_S$. Then $b^{NI} = V_S$ and $\Pi^{NI} = V_P - V_S$. On the other hand, P's payoff in BI cannot exceed $V_P - V_S$, since $[\kappa_H F_H(p_H) + \kappa_L F_L(p_L)](V_P - b) - X_0 \leq [\kappa_H F_H(p_H) + \kappa_L F_L(p_L)](V_P - b - X_0) \leq V_P - V_S$. This

completes the proof.

Proof of Proposition 3:

(a) Here we show that any allocation achieved with BI only for state η_i , with no trade between P and S in the other state η_j generates strictly lower payoff than Π^{BI} . Since S earns at least u_i^S in η_i , an upper bound to P's payoff is

$$\kappa_i[F_i(p_i(V_P))(V_P - p_i(V_P)) - u_i^S] \quad (10)$$

where $p_i(V_P) \equiv \arg \max_{p_i \in [0,1]} F_i(p_i)(V_P - p_i)$.³¹

We show that Π^{BI} is strictly greater than (10). Without loss of generality, we can restrict attention to situations where (10) is positive, or equivalently

$$V_P > p_i(V_P) + \frac{u_i^S}{F_i(p_i(V_P))}.$$

We consider two cases: (Case 1) $p_i(V_P) + \frac{u_i^S}{F_i(p_i(V_P))} \geq p_j(V_P) + \frac{u_j^S}{F_j(p_j(V_P))}$ and (Case 2) $p_i(V_P) + \frac{u_i^S}{F_i(p_i(V_P))} < p_j(V_P) + \frac{u_j^S}{F_j(p_j(V_P))}$.

Case 1

Consider allocation $(p_i, p_j, b, X_0) = (p_i(V_P), p_j(V_P), p_i(V_P) + \frac{u_i^S}{F_i(p_i(V_P))}, 0)$. P's payoff in this allocation is

$$\kappa_i[F_i(p_i(V_P))(V_P - p_i(V_P)) - u_i^S] + \kappa_j F_j(p_j(V_P))(V_P - b),$$

which is strictly greater than (10) since $V_P > b$. We need to check that this allocation satisfies all conditions in Lemma 1. (2, 3, 4) are obviously satisfied from the

³¹P can design the BI mechanism which exactly achieves (10) in an equilibrium. Consider the BI mechanism as follows. In state i , S receives $b - p_i + X_0$ (or X_0) for the delivery (or non-delivery) of the good, while A does p_i (or none) for the delivery (or non-delivery). In state j ($j \neq i$), S receives $b - p_j + X_0 - u_{A_j}$ (or $X_0 - u_{A_j}$) and A does $p_j + u_{A_j}$ (or u_{A_j}) for the delivery (or non-delivery). In the non-cooperative play of the mechanism, the truthful telling of each state (i or j) is ensured by the cross checking scheme. P can select u_{A_j} such that S prefers to reject BI offer only in j . It is easy to find (p_i, p_j, b, X_0) which achieves (10), satisfying all conditions.

construction. Since $u_i^S \geq F_i(p_i(V_P))(V_S - p_i(V_P))$ implies $b + X_0 = b \geq V_S$ or (1). The selection of b implies $b \geq \max\{p_i(V_P), p_j(V_P)\} \geq \max\{\hat{l}_i(p_i(V_P)), \hat{l}_j(p_j(V_P))\}$. If $p_i(V_P) < \bar{\theta}$, $h_i(p_i(V_P)) = V_P > p_i(V_P) + \frac{u_i^S}{F_i(p_i(V_P))} = b$. Similarly if $p_j(V_P) < \bar{\theta}$, $h_j(p_j(V_P)) = V_P > b$. This argument guarantees (8).

Case 2

By the definition of u_j^S , $u_i^S = F_i(p_i(V_S))(V_S - p_i(V_S)) \geq F_i(p_i(V_P))(V_S - p_i(V_P))$ implies

$$p_j(V_P) + \frac{u_j^S}{F_j(p_j(V_P))} > p_i(V_P) + \frac{u_i^S}{F_i(p_i(V_P))} \geq V_S = p_j(V_S) + \frac{u_j^S}{F_j(p_j(V_S))}.$$

Since $p_j(V_S) < p_j(V_P)$, there exists $\hat{p}_j \in [p_j(V_S), p_j(V_P))$ such that

$$\hat{p}_j + \frac{u_j^S}{F_j(\hat{p}_j)} = p_i(V_P) + \frac{u_i^S}{F_i(p_i(V_P))}$$

and

$$d[p_j + \frac{u_j^S}{F_j(p_j)}]/dp_j |_{p_j=\hat{p}_j} = 1 - \frac{u_j^S f_j(\hat{p}_j)}{F_j(\hat{p}_j)^2} \geq 0.$$

Obviously $\hat{p}_j > \underline{\theta}$. The latter condition can be rewritten as

$$h_j(\hat{p}_j) \geq \hat{p}_j + \frac{u_j^S}{F_j(\hat{p}_j)}.$$

Consider allocation $(p_i, p_j, b, X_0) = (p_i(V_P), \hat{p}_j, p_i(V_P) + \frac{u_i^S}{F_i(p_i(V_P))}, 0)$. P's payoff in this allocation is

$$\kappa_i[F_i(p_i(V_P))(V_P - p_i(V_P)) - u_i^S] + \kappa_j F_j(\hat{p}_j)(V_P - b),$$

which is strictly greater than (10) since $V_P > b$ and $\hat{p}_j > \underline{\theta}$. (2, 3, 4) are obviously satisfied. The same argument as (Case 1) can apply to show (1), $b \geq \max\{\hat{l}_i(p_i(V_P)), \hat{l}_j(\hat{p}_j)\}$ and $h_i(p_i(V_P)) > b$ for $p_i(V_P) < \bar{\theta}$. We also have already checked that $h_j(\hat{p}_j) \geq \hat{p}_j + \frac{u_j^S}{F_j(\hat{p}_j)} = b$, guaranteeing (8). This completes the proof of (a).

We now prove (b). Suppose that the optimal payoff is achieved with NI for signal state i ($i = L, H$) and BI for signal state j ($j \neq i$). Then optimal allocation $(p_i^*, p_j^*, b^*, X_0^*)$ satisfies $h_i(p_i^*) = b^*$ and $p_i^* < \bar{\theta}$, since $b^* < V_P < h_H(\bar{\theta}) < h_L(\bar{\theta})$. Now consider a small rise of p_i from p_i^* to p_i^{**} such that $p_i^{**} = p_i^* + \epsilon < \bar{\theta}$ with $\epsilon > 0$. X_0 is also raised from X_0^* to

$$X_0^{**} = F_i(p_i^*)(b^* - p_i^*) + X_0^* - F_i(p_i^{**})(b^* - p_i^{**}).$$

Notice that X_0^{**} is greater than X_0^* since p_i^* maximizes $F_i(p_i)(b^* - p_i)$. Now consider allocation $(p_i^{**}, p_j^*, b^*, X_0^{**})$. It is evident that P's payoff in this allocation is greater than that in the original one for sufficiently small ϵ . We can also check that this allocation satisfies all conditions in Lemma 1 for sufficiently small ϵ . This completes the proof of Proposition 3.

Proof of Proposition 4: Let p^* be the maximizer of $F(p)(V_P - p)$. Then $p_L(V_S) < p^* < \bar{\theta}$ from our conditions. First it is shown that $p^{NS} < \bar{\theta}$ (or interior solution) under $H(\bar{\theta}) > V_P > V_S > \underline{\theta}$. We can consider two cases: $u_L^S \geq V_S - p^*$ and $u_L^S < V_S - p^*$:

- (i) If $u_L^S \geq V_S - p^*$ (which occurs with small V_S), $X_0 + p \geq V_S$ is not binding. Then the solution is $(p^{NS}, X_0^{NS}) = (p^*, u_L^S)$. It also implies $p^{NS} < \bar{\theta}$.
- (ii) If $u_L^S < V_S - p^*$, the second constraint is binding in the solution or $X_0^{NS} + p^{NS} = V_S$. Then $X_0^{NS} = V_S - p^{NS} \geq u_L^S$. Since $V_S - \bar{\theta} < u_L^S$ with $p_L(V_S) < p^* < \bar{\theta}$, $p^{NS} < \bar{\theta}$.

Next let us consider allocation $(p_L, p_H, b, X_0) = (p^{NS}, p^{NS}, p^{NS}, X_0^{NS})$ as a starting point. It is evident that this satisfies all constraints of BI problem and generates Π^{NS} to P. Now we consider a small variation from this allocation to

$$(p'_L, p'_H, b', X'_0) = (p^{NS}, p^{NS} + \epsilon, p^{NS}, X_0^{NS}).$$

Since $u_L^S > u_H^S$ for $V_S > 0$, this satisfies

$$F_H(p'_H)(b' - p'_H) + X'_0 = -\epsilon F_H(p^{NS} + \epsilon) + X'_0 \geq -\epsilon F_H(p^{NS} + \epsilon) + u_L^S \geq u_H^S$$

for sufficiently small $\epsilon > 0$. It means that this allocation also satisfies all constraints of the problem in BI, and P's payoff is greater than Π^{NS} .

Proof of Proposition 5: Suppose that P offers $\{(b_i, X_i, p_i) \mid i = L, H\}$ to S in NI. For S's report of $\eta = \eta_i$, this specifies payments to S ($b_i + X_i$ and X_i) for the delivery and the non-delivery, and also price p_i paid from S to A. Without loss of generality, our attention is restricted to a mechanism which induces the S's participation and truthful telling of η , which satisfies the following conditions:

$$F_i(p_i)(b_i - p_i) + X_i \geq u_i^S$$

and

$$F_i(p_i)(b_i - p_i) + X_i \geq F_i(p_j)(b_j - p_j) + X_j.$$

We check that the second-best allocation is achievable in this mechanism. The second-best allocation requires $p_i = p_i^{SB} \equiv p_i(V_P)$ and $F_i(p_i^{SB})(b_i - p_i^{SB}) + X_i = u_i^S$ to be satisfied for $i = L, H$. These conditions are equivalent to (b_L, b_H) which satisfies

$$u_L^S \geq u_H^S + [F_L(p_H^{SB}) - F_H(p_H^{SB})](b_H - p_H^{SB})$$

and

$$u_H^S \geq u_L^S + [F_H(p_L^{SB}) - F_L(p_L^{SB})](b_L - p_L^{SB}).$$

Our assumption ($V_P < h_L(\bar{\theta})$) implies $p_L^{SB} < \bar{\theta}$ and $F_H(p_L^{SB}) < F_L(p_L^{SB})$. These conditions are satisfied at $b_H = p_H^{SB}$ and

$$b_L \geq p_L^{SB} + \frac{u_L^S - u_H^S}{F_L(p_L^{SB}) - F_H(p_L^{SB})}.$$
