Supporting Information

Abstract: Understanding the influence of macromolecular crowding and nanoparticles on the formation of in-register β-sheets, the primary structural component of amyloid fibrils, is a first step toward describing in vivo protein aggregation and interactions between synthetic materials and proteins. Using all-atom molecular simulations in implicit solvent, we illustrate the effects of nanoparticle size, shape, and volume fraction on oligomer formation of an amyloidogenic peptide from the transthyretin protein. Surprisingly, we find that inert spherical crowding particles destabilize in-register β-sheets formed by dimers while stabilizing β-sheets comprised of trimers and tetramers. As the radius of the nanoparticle increases, crowding effects decrease, implying that smaller crowding particles have the largest influence on the earliest amyloid species. We explain these results using a theory based on the depletion effect. Finally, we show that spherocylindrical crowders destabilize the ordered β-sheet dimer to a greater extent than spherical crowders, which underscores the influence of nanoparticle shape on protein aggregation.

Section: Nanoparticles and Nanostructures

Molecular crowding can have a profound effect on virtually all biological processes such as protein folding, viral capsid assembly, and protein aggregation.1–6 It is estimated that 20–30% of a typical cell’s volume is occupied by DNA, protein, lipids, and sugars.7 Such a crowded environment restricts the conformations explored by biological macromolecules, thus affecting the balance of thermodynamic forces that help regulate cellular processes. More recently, it has also been realized that synthetic nanoparticles (NPs) such as quantum dots, carbon nanotubes, and gold and other colloidal particles also affect the stability and function of proteins.8–10 Understanding nanoparticle–protein interactions is important in our ability to use NPs for drug delivery and controlling environmental toxicity.11

In the context of aggregation of amyloidogenic peptides, which is the focus of the present study, NPs can greatly influence the stabilities of the molecular species that accumulate along the routes to fibril formation. Amyloid fibrils are experimentally characterized as cross-β structures that are rich in β-sheet content.17–19 Formation of amyloid is linked to a number of human diseases,18,20 and it appears that almost any polypeptide chain can form amyloid under appropriate solution conditions.18 Even small peptides,21 such as the fragment comprised of residues 105–115 from the transthyretin (TTR) protein, form amyloid fibrils.22,23 TTR fibrils are associated with senile systemic amyloidosis and familial amyloid polyneuropathy.1

General theoretical arguments based on the depletion effect3,4,24–27 suggest that monodisperse spherical NPs should promote protein aggregation. The depletion effect, which results in nonspecific entropy-induced attraction between proteins in the presence of nonadsorbing NPs, arises from the volume excluded to the NPs by the monomer subunits of aggregating proteins. Consider, for example, two proteins that are spherical with a radius $R_N$. When two such proteins approach each other up to a distance on the order of the radius, $R_N$, of the crowding particles, the particles can no longer fit and are therefore expelled from the gap formed by the proteins. Thus, the crowding particles exert an osmotic pressure on the associating monomers, resulting in a net interprotein attraction.24–26 As a result, inert crowding particles promote protein–protein association, which is in accord with several experiments.

Although this qualitative argument is compelling, the molecular consequences of crowding effects on oligomer formation are unknown. In particular, it is unclear whether crowding particles...

stabilize ordered β-sheet oligomers, which might facilitate amyloid formation, or stabilize amorphous aggregates with little β-sheet content, which would likely impede or delay amyloid formation. To address these unresolved issues, we have carried out molecular simulations of systems composed of either two, three, or four TTR peptides to assess the effect of the size, shape, and volume fraction (Φ_C) of NPs on the structural and energetic properties of TTR oligomers. We find that spherical NPs destabilize ordered dimer aggregates but stabilize trimer and tetramer ordered aggregates. Increasing the radius of the NP, at a fixed crowder volume fraction, reduces the effect of molecular crowding due to an increase in the interstitial space between NPs. In contrast, increasing the aspect ratio of the NPs with a spherocylinder shape leads to greater destabilization of the ordered dimer than a spherical crowding particle.

In order to assess the effect of crowders on oligomer formation, we first carried out separate constant-temperature simulations on the monomer, dimer (denoted \{TTR\}_2), trimer (\{TTR\}_3), and tetramer (\{TTR\}_4) systems in the EEF1.1 implicit solvent model at Φ_C = 0, a temperature of 395 K, and a protein concentration of around 30 mM (Supporting Information Table 1). A high temperature was used to increase conformational sampling and yield converged results; we found that simulations carried out at temperatures less than 330 K were not converged. It should be stressed that for a complete understanding of crowding effects, peptide concentration must also be varied, as has been recently demonstrated in a complementary study using model systems. For the systems containing two or more peptides, we find that due to the high protein concentration, the peptides are associated. Therefore, we cannot examine the effect of NPs on the association process of these peptides. However, as mentioned previously, the more crucial aspect from the perspective of amyloid formation is determining the effect of NPs on the different aggregated species (ordered versus disordered), an issue which these simulations can directly address.

The TTR monomer is compact and devoid of persistent secondary structure at Φ_C = 0. Its average radius of gyration is 7 Å, whereas a fully extended TTR structure would have a value of around 12 Å. Analysis of the secondary structure content shows that coil and turn structures are the most prevalent, while helical and β-strand structures are negligibly populated (<2%). Even in the presence of crowding agents, the strand content does not change appreciably. Thus, in isolation, the TTR peptide is unstructured.

Figure 1. Effect of spherical crowding on \{TTR\}_n as a function of Φ_C. (A) and (B) are for the \{TTR\}_2. (A) Secondary structure content (β-strand (black), random coil (red), or turn(green)) versus Φ_C. Example structures from the ordered aggregate and disordered aggregate are displayed in the upper left and right, respectively. (B) The fraction of in-register contacts (P_{IR}; see eq 4 in the Supporting Information) versus Φ_C. (C) and (D) correspond to data from the \{TTR\}_3 and \{TTR\}_4 systems. (C) The Φ_C-dependent changes in the β-strand content for the trimer (solid black line with circles) and the tetramer (dashed red line with squares). (D) Same as (C) except that the ordinate is the probability of finding an in-register aggregate (including both parallel and antiparallel configurations).
The radius of gyration \( R_g \) of the individual peptides in the ordered \( \{\text{TTR}\}_3 \) ("ordered" being defined as having greater than 8 in-register contacts out of a possible 11) is 10.8 Å, while \( R_g \) of the peptide in the disordered \( \{\text{TTR}\}_2 \) conformations (which have less than 5 in-register contacts) is 6.7 Å. Independent simulations of the \( \{\text{TTR}\}_3 \) and \( \{\text{TTR}\}_4 \) at \( \Phi_C = 0 \) reveal that they also exist as either disordered aggregates or ordered \( \beta \)-sheets. However, the probabilities of a \( \beta \)-sheet structure, which includes out-of-register \( \beta \)-strands, for \( \{\text{TTR}\}_3 \) and \( \{\text{TTR}\}_4 \) are 0.52 and 0.44, respectively (Figure 1c). The probabilities that \( \{\text{TTR}\}_3 \) and \( \{\text{TTR}\}_4 \) form ordered in-register parallel and antiparallel strand arrangements are 0.30 and 0.06, respectively (Figure 1d). The decrease in ordered in-register \( \beta \)-sheets, relative to the \( \{\text{TTR}\}_2 \) system, is due to an increase in the number of low-energy out-of-register disordered conformations that are accessible as the number of peptides in the aggregate increases. Thus, the landscape of TTR oligomers has a number of distinct basins of attraction with conformationally heterogeneous structures (see also ref 33).

We next examined the influence of inert spherical NPs with \( R_C = 3.5 \) Å (\( \Phi_C > 0 \), Figure 2a). For the \( \{\text{TTR}\}_2 \) system, the presence of spherical NPs decreases the stability of the expanded (conformations with \( R_g > 10 \) Å) dimer structures monotonically as \( \Phi_C \) increases, while the stability of the collapsed structures (i.e., \( R_g < 7.5 \) Å) increases (Figure 2b). As a consequence, the average solvent-accessible surface area and the molecular volume of the dimer decrease as \( \Phi_C \) increases (data not shown). In addition, the \( \beta \)-strand content (Figure 1a) and the probability of finding polymerization-competent in-register dimers (\( P_{\text{IR}} \)) decreases with increasing \( \Phi_C \) (Figure 1b). Thus, relative to \( \Phi_C = 0 \), crowding destabilizes in-register \( \beta \)-sheet aggregates, causing the equilibrium to shift toward collapsed associated dimer structures at all values of \( \Phi_C \) (see the structures in Figure 1a).

Surprisingly, we find the opposite result for the \( \{\text{TTR}\}_3 \) and \( \{\text{TTR}\}_4 \), whose ordered structures are stabilized as \( \Phi_C \) increases. The \( \beta \)-strand content in \( \{\text{TTR}\}_3 \) remains the same as \( \Phi_C \) increases, whereas there is a slight increase for \( \{\text{TTR}\}_4 \) (Figure 1c). In addition, \( P_{\text{IR}} \) increases for the trimer and tetramer with increasing \( \Phi_C \) (Figure 1d). The observed variations in crowding-induced changes in the stabilities of the ordered \( \beta \)-sheet aggregates may be relevant to in vivo amyloid formation as \( \beta \)-sheets are the primary structural component found in mature fibrils.21,34–36 In particular, NPs may inhibit the ordered dimer structures but stabilize higher-order oligomers.

This nonmonotonicity in the \( n \) dependence of the stability of the ordered aggregate of \( \{\text{TTR}\}_n \) (\( n = 2, 3, 4 \)) at various \( \Phi_C \) can be explained using a theory based on depletion forces. Scaled Particle Theory37–39 suggests that a factor influencing crowder effects is the free-energy cost of creating a void within the configuration of NPs to accommodate \( \{\text{TTR}\}_n \) when \( \Phi_C \neq 0 \). The free energy is a function of volume of the \( \{\text{TTR}\}_n \)’s volume, which increases as \( n \) becomes larger. Clearly, the probability of finding a volume to accommodate \( \{\text{TTR}\}_n \) decreases as \( n \) increases. Depletion-induced changes in the free energy of the ordered aggregate relative to the disordered aggregate, denoted \( \Delta G_{\text{a}} \), is therefore proportional to \( \ln(V_{\text{OA}}/V_{\text{DA}}) \), where \( V_{\text{OA}} \) (\( V_{\text{DA}} \)) is the volume excluded to the NP’s center-of-mass (also known as the “depletion volume”) by the ordered (disordered) aggregate. Peptide conformational entropy changes also likely contribute to the behavior of \( \Delta G_{\text{a}} \) with \( n \). However, it is difficult to accurately estimate these entropy changes in the ordered and disordered aggregates due to crowding. In addition to conformational entropy differences, stability is also determined by favorable enthalpic interpeptide interactions. Enthalpic stabilization occurs for both the ordered and disordered aggregates as \( n \) increases because of an increase in the number of interpeptide contacts. The specific value of \( n \) that stabilizes the ordered form should depend on the size and sequence of the peptide. For \( \{\text{TTR}\}_n \), it is only when \( n \) becomes larger than 3 that the ordered aggregate structures become more stable in the presence of spherical NPs (Figure 1b and d).

If depletion forces are a major factor in the nonmonotonic behavior of \( \Delta G_{\text{a}} \) with \( n \), then we can account for the simulation results using the changes in the volume excluded to the NPs. From the Asakura–Oosawa (AO) theory24 and a microscopic formulation,25 as well as several other approaches,37–39 it follows that the difference in free energy between species \( i \) and \( j \) is \( \Delta G(n) = P(V_{\text{ex}}(n)/V_{\text{ex}}(\text{null})) \), where \( P = k_B T \Phi_C/V_C \) is the osmotic pressure under ideal solution conditions, \( k_B \) is Boltzmann’s constant, \( V_C \) is the molecular volume of a nanoparticle, and \( V_{\text{ex}}(n) \) is the volume excluded to the spherical nanoparticle by species \( i \). There are three relevant species in the \( \{\text{TTR}\}_n \) system, the soluble nonassociated monomers (SM), the disordered aggregate (DA), and the ordered aggregate (OA). We calculate \( V_{\text{ex}}(n) \) by assuming that the soluble monomers and disordered aggregate are hard spheres whose radii depend on \( n \). In this case,

\[
V_{\text{ex}}^\text{SM}(n) = \frac{4\pi n}{3} \left[ (1.927N_\text{aa}^0.6 + R_g^3) - (1.927N_\text{aa}^0.6)^3 \right]
\]
Figure 3. (A) Theoretical prediction of the stability of the ordered β-sheet aggregate relative to the disordered aggregate as a function of the number of TTR peptides in the system. The solution conditions in this theoretical treatment are \( T = 395 \text{ K} \), \( \Phi_C = 0.15 \), and \( R_C = 30 \text{ Å} \). (B) Volume excluded (i.e., the depletion volume) to the NPs center of mass of the soluble monomers (green triangles), disordered aggregate (red squares), and ordered β-sheet aggregate (black circles) calculated from eqs 1–3.

\[
V_{\text{ex}}(n) = \frac{4\pi}{3}\left[1.927(n\cdot N_{aa})^{0.6} + R_C^3\right] - \left(1.927(n\cdot N_{aa})^{0.6}\right)^3
\]

(2)

where \( N_{aa} \) is the number of amino acids in the peptide and the exponent of 0.6 is the Flory scaling exponent that characterizes the size of a protein in a good solvent.\(^{40}\) The shape of the ordered β-sheet aggregate is taken to be a stacked rectangular parallelepiped, where each parallelepiped corresponds to one TTR peptide. For this species, \( V_{\text{ex}} \) is computed using

\[
V_{\text{ex}}(n) = (l + 2R_C)(w + 2R_C)(h + 2R_C) - \text{shape} - \left(8R_C^3 - \frac{4}{3}\pi R_C^3\right)
\]

(3)

where \( l \), \( w \), and \( h \) correspond to the length, width, and height of a β-sheet made up of \( n \) peptides, respectively. Therefore, we define \( l = 3.2\cdot N_{aa} \text{ Å} \), corresponding to the length of an extended β-strand made up of \( N_{aa} \) amino acids; \( w = 8 \text{ Å} \), which corresponds to the distance that the side chains stick out above and below the β-sheet; \( h = 4.85n \text{ Å} \), where 4.85 Å corresponds to the experimentally determined distance between the neighboring strands in a β-sheet.

Using eqs 1–3, it is straightforward to compute the \( V_{\text{ex}} \) for each species at different \( \Phi_C \) and thereby estimate \( \Delta G(n) \) at a given \( \Phi_C \). We find that indeed for a range of \( R_C \) values, this model displays nonmonotonic behavior (Figure 3a) consistent with the trends observed in the simulations; the ordered dimer is destabilized by spherical crowders, but as more peptides are added, the NPs stabilize the ordered β-sheet aggregates. The physical origin of this unusual behavior arises because the disordered dimer aggregate excludes less volume than the ordered dimeric β-sheet (Figure 3b), but as additional peptides are added to the system, the volume per peptide increases to a greater extent in the disordered aggregate than that for the ordered β-sheet (the same observation was made in ref 41). As a consequence, the free energy of the system is minimized when the dimer is disordered, whereas NP-induced ordered trimer and tetramer structures are more stable. Recapitulation of the qualitative trends observed in the simulation model suggests that the depletion effect explains the changes in nanoparticle-induced changes in stability as \( n \) varies.

There are a number of other parameters besides \( \Phi_C \) that also influence oligomerization. For example, what happens when the radius of the NPs increases? For a fixed peptide concentration (\([C_P]\)) and \( \Phi_C \), larger NPs exclude less volume to the protein than smaller crowders because the interstitial space between crowders increases with crowder size. It can be shown that the strength of the depletion force is proportional to \( (1/R_C)^2 \). Therefore, larger crowding particles should have a smaller effect in altering the stability of [TTR] \(_4\). Explicit simulations that we ran of [TTR] \(_4\) at \( \Phi_C = 0.15 \) using three spherical NP sizes \( (R_C = 3.5, 6, \text{ and } 11 \text{ Å}) \) show that indeed as \( R_C \) increases, larger crowders shift the equilibrium toward expanded structures (Figure 4). However, in the simulations, we observe that the average β-sheet content does not exhibit an increase as the size of the NP increases, and the probability \( \sim 0.06 \) of finding ordered in-register dimers is also unchanged. Thus, increasing \( R_C \) of spherical NPs decreases the impact of crowding, a result consistent with other theoretical and simulation modeling.\(^{42}\)

Another variable that controls the extent or ordered oligomer formation is the shape of the crowding particles. Indeed, in vivo most naturally occurring molecular crowders are unlikely to be spherical. Analysis of protein structures in the Protein Data Bank\(^{43}\) show that even in the folded state, proteins adopt anisotropic shapes. To explore the effect of NP shape on dimer stability, we simulated the [TTR] \(_4\) system in the presence of spherocylindrical NPs in the isotropic phase whose aspect ratio \( =L/D+1 \), where \( L \) is the spherocylinder length and \( D \) is its diameter) is 3.3. We find that for the same \( \Phi_C \) value (below \( \Phi_C \approx 0.1 \), which is below the isotropic to nematic transition point), spherocylindrical NPs cause a greater loss of β-strand content in the dimer than that in spherical NPs. Thus, spherocylindrical NPs destabilize ordered oligomers. This suggests that anisotropic NPs may have a greater impact on amyloid formation than spherical NPs and that crowder shape is another important variable in understanding amyloid formation in vivo. To further explore realistic models of oligomerization in the cellular context, it would be important to consider a soup of proteins, as was done recently to explore folding and diffusion in models of \( E. \), coli.\(^{44}\)

Although the systems investigated in this study are caricatures of cellular crowding, they illustrate the complexity of peptide aggregation under in vivo conditions. While generic arguments suggest that depletion forces should promote protein association, our work shows that the structures of the oligomers can be dramatically altered by the size, shape, and volume fraction of the nanoparticles. Our study shows that an interplay of a number of factors determines the equilibrium between the ordered and...
Changes in the free-energy profile as a function of $R_c$ of the monomer (within the dimer) as the radius $R_c$ of the spherical NP is varied. disordered oligomeric structures. For spherical NPs, the variables that determine the depletion forces, and hence the strength and range of the entropically induced interpeptide attraction, are $q = (R_c/R)$ (where $R$ is the size of the peptide monomer), $[C_p]$ the peptide concentration, and $\Phi_C$.

This predicted complexity in the crowding-induced diagram of states of the amyloidogenic peptide is not surprising given that in the field of polymer physics, it was discovered previously that the phase diagram of a mixture of hard-sphere colloidal particles and self-avoiding polymers in an erticular solvent is complicated and depends on polymer concentration, $\Phi_C$, and $q$. For the TTR peptides and $R_c$ values examined here, $q$ ranges in value from 0.6 up to 2 (note that $R_c \approx 7$ Å for the peptide monomer). It follows from our work that larger $q$ values can promote extended peptide conformations with high $\beta$-strand content in aggregates consisting of more than two peptides. Conversely, in the extreme case of $q \ll 1$ (in the so-called colloid limit\textsuperscript{26}), we predict that the influence of crowding effects will be decreased, and the equilibrium between ordered and disordered species may not be significantly perturbed relative to bulk ($\Phi_C = 0$).

The results presented here show that understanding of NP effects on protein aggregation requires determination of a global phase diagram in terms of a number of variables. The nonmonotonicity in NP-induced changes in stability should be contrasted with the effect of crowding on monomeric protein folding stability, which monotonically increases in the presence of nonadsorbing crowding particles.\textsuperscript{7} Further insights into in vivo aggregation will require extension of the present work by taking crowder phase and polydispersity into account perhaps along the lines suggested recently.\textsuperscript{15} In such a complex environment, polydispersity and concentration fluctuations could drive phase separation in the macromolecules,\textsuperscript{14} which could add additional complications in the process of protein aggregation.

\section*{METHODS}

\textbf{Models for the Peptide and Solvent.} We chose the peptide fragment (sequence Tyr-Thr-Ile-Ala-Leu-Leu-Ser-Pro-Tyr-Ser) from the transthyretin protein (TTR) corresponding to residues 105–115. The structure of these 12 residues in an amyloid fibril has been determined (PDB ID 1RVS) using solid-state NMR.\textsuperscript{22,23} We capped the peptide’s N-terminus with an acetyl blocking group and its C-terminus with an amine blocking group (NH$_2$). For the peptide we used an all-atom representation except for nonpolar hydrogen atoms, which are omitted in the calculations. The EEF1.1 implicit solvent model\textsuperscript{46} is used to account for solvent effects in conjunction with the CHARMM19 force field.\textsuperscript{31}

\textbf{EEF1.1 Implicit Solvent Model.} The parametrization of the EEF1.1\textsuperscript{31} force field required the use of specific cutoff distances for nonbonded interactions. The Lennard-Jones (LJ) and electrostatic interactions were truncated at 9 Å, with a switch function applied to the LJ term starting at 7 Å. The Lorentz–Berthelot mixing rules\textsuperscript{47} were used to determine the undefined $\sigma$ values between the atomic centers in the peptide. A distance-dependent dielectric constant was used for electrostatic interactions.

The LJ interactions in the EEF1.1 protein parameters are restricted to a distance less than 9 Å, which prevents us from studying crowders with $R_c$ values greater than 4.5 Å in the standard Charmm code. We modified the CHARMM code to allow the LJ cutoff to be dependent on the identity of the interacting atomic centers, thereby allowing us to use larger crowding particles. For protein–protein interactions, nonbonded interactions were truncated at 9 Å, but for crowder–crowder and crowder–protein interactions we used a cutoff of 2$R_c + 2$ Å and $R_c + 2$ Å, respectively. These procedures allow us to maintain the EEF1.1 nonbond requirements for protein–protein interactions while allowing for larger crowding particles to be simulated.

\textbf{Simulation Details.} Simulations were carried out in the NVT ensemble at 395 K using Langevin dynamics with a friction coefficient of 1 ps$^{-1}$. This high temperature allowed the dimer simulations to reach equilibrium, whereas simulations at 330 K were found to not have converged on our simulated time scales (data not shown). The SHAKE algorithm was used to fix the bond lengths of covalently bonded hydrogen, allowing the use of a 2 fs time step.

Typically, we generated 10 independent trajectories for each crowder size and $\Phi_C$. At least half of the trajectories were started with peptide conformations taken from equilibrated bulk simulations at $\Phi_C = 0.0$. When possible, the other five starting conformations were taken from solution conditions that were closest to those of interest. For example, when simulating crowders with $R_c = 6$ and 11 Å, half of the initial protein conformations were from the equilibrium simulations of crowders with $R_c = 3.5$ Å and $\Phi_C = 0.15$.

A box length of 60.0 to 80.0 Å was used for all spherical NP conditions, which gave a peptide concentration in the range from 15 to 31 mM. At $\Phi_C = 0.05, 0.10, 0.15$, and 0.20, there were...

Lennard-Jones particles. The interaction between sites i and j on
two distinct NPs is

\[ V_{ij}(r_{ij}) = 4\varepsilon \left( \frac{\sigma}{r_{ij}} \right)^{12} - \left( \frac{\sigma}{r_{ij}} \right)^{6} \]  

(4)

The choice of \( \varepsilon = 10^{-15} \) kcal/mol makes eq 4 essentially
repulsive, and the condition \( V_{ij}(r_{ij} = 2R_C) = k_B T \) allows us to
solve for \( \sigma \). We consider three values for \( R_C = 3.5, 6, \) and 11 Å,
which leads to \( \sigma = 108.7, 186.3, \) and 341.6 Å, respectively.

Model for Spherocylinders and Crowder—Protein Interactions.

We define all protein—crowder \( \sigma \) values such that when a
crowding particle interaction site is \( (R_C + 1) \) Å from a protein
atomic center, \( V_{ij}(R_C + 1) = k_B T \). The resulting \( \sigma \) values are
139.7, 217.4, and 372.6 Å for \( R_C = 3.5, 6, \) and 11 Å, respectively.

The covalent bond between the tethered spheres that com-
prise the spherocylinder was modeled using

\[ V_B(r) = k_B / 2(r_o - r)^2 \]  

(5)

where \( k_B = 30 \) kcal/(mol·Å²) and \( r_o = 4 \) Å is the equilibrium
bond length. The rigidity of the spherocylinder is maintained
using a bond angle potential

\[ V_A(\theta) = k_A / 2(\theta_o - \theta)^2 \]  

(6)

with \( \theta_o = 180^\circ \) and \( k_A = 0.6092 \) kcal/degree². An important
characteristic of a spherocylinder is the aspect ratio \( \lambda \). A value of
\( \lambda = 1 \) corresponds to a spherical crowder with diameter \( D = 2R_C \).
In our study, all spherocylinders have \( R_C = 3.5 \) Å, and \( L_C \), which is
proportional to the number of spheres \( (N_B) \) in the spherocyl-
inder. \( L_C = (N_B - 1) \times 4.0 \) Å. We used \( \lambda = 3.3 \), corresponding to a
spherocylinder made up of five beads.
