Breakdown Probabilities for Thin Heterostructure Avalanche Photodiodes

Majeed M. Hayat, *Senior Member, IEEE*, Ünal Sakoğlu, *Student Member, IEEE*, Oh-Hyun Kwon, Shuling Wang, Joe C. Campbell, *Fellow, IEEE*, Bahaa E. A. Saleh, *Fellow, IEEE*, and Malvin C. Teich, *Fellow, IEEE*

***Abstract*—The recurrence theory for the breakdown probability in avalanche photodiodes (APDs) is generalized to heterostructure APDs that may have multiple multiplication layers. The generalization addresses layer-boundary effects such as the initial energy of injected carriers as well as the layer-dependent profile of the dead space in the multiplication region. Reducing the width of the multiplication layer serves to both downshift and sharpen the breakdown probability curve as a function of the applied reverse-bias voltage. In structures where the injected carriers have an initial energy that is comparable to the ionization threshold energy, the transition from linear mode to Geiger-mode is more abrupt than in structures in which such initial energy is negligible. The theory is applied to two recently fabricated $Al_{0.6}Ga_{0.4}As$–GaAs heterostructure APDs and to other homostructure thin GaAs APDs and the predictions of the breakdown-voltage thresholds are verified.**

***Index Terms*—Bandgap-boundary effects, breakdown probability, breakdown voltage, dead space, heterostructues, impact ionization, thin avalanche photodiodes.**

I. Introduction

Avalanche photodiodes (APDs) are highly desirable in fiber-optic communication systems and in many applications that rely on precision radiometric measurements such as photon and photon-coincidence counting. Recently, APDs with thin multiplication layers have been shown to exhibit a significant reduction in the excess noise factor, a feature that is now well known to be attributable to the dead-space effect [1]–[8]. The dead space is the distance a carrier must travel within the APD's multiplication region before acquiring the energy threshold needed for effecting an impact ionization. In essence, dead space results in inhibition in the locations of ionization, which, in turn, brings about orderliness in the avalanche of carrier generation. In APDs with wide multiplication regions (*viz.*, >0.4 μm), the dead-space distance is negligible relative to the width and its effect on the carrier multiplication is minimal. However, in thin APDs, the dead space can occupy a large fraction of the multiplication region, thereby significantly altering not only the multiplication noise but also the time response, power spectral density, and breakdown [4], [9], [10]. Heterostructure APDs with multiple thin multiplication layers have also been recently fabricated, exhibiting even lower excess noise factors. Such improved performance has been attributable to the combination of the dead-space effect and bandgap-boundary effects, which can serve to further regularize impact ionization through careful bandgap engineering [11]–[13].

One aspect of the APD performance whose dependence on the dead space was not analytically investigated is the breakdown probability. Breakdown occurs when the APD's gain becomes infinite. In general, as the applied reverse-bias voltage is raised beyond a threshold, the probability that the gain becomes unstable diverges from zero, and gradually approaches unity as the voltage is further raised. In fact, this threshold voltage is nothing but the breakdown voltage, which is defined as the applied reverse-bias voltage at which the *mean* gain becomes infinite. (Note that as the gain is integer-valued, its mean is finite if and only if the probability of having an infinite gain is zero.) The behavior of the breakdown probability, as a function of the applied revere-bias voltage, is the key indicator of how fast the transition from stable to saturated operation occurs. For example, when an APD is used in the Geiger mode, it is highly desirable that such a transition occur as rapidly as possible so that any incoming photon triggers a measurable response with near certainty. On the other hand, if the transition is not steep, then at any given applied reverse bias, a fraction of the absorbed photons (proportional to the complement of the breakdown probability) will fail to trigger breakdown, which reduces detection efficiency.

In light of the role played by the multiplication-region width in improving the noise and bandwidth characteristics in thin APDs, a natural question that comes to mind is whether thin APDs exhibit improved breakdown characteristics. We have partially answered this question affirmatively in the past by showing that the breakdown voltage decreases as the width decreases [9]. However, the breakdown probabilities for thin APDs have not been investigated heretofore. In 1999, McIntyre [7] adopted the recurrence principles developed by Hayat *et al.* [1], [14] and formulated recurrence equations which characterized the breakdown probability for the case of nonuniform fields. Although McIntyre [7] attempted to predict the breakdown probability, he encountered difficulty in numerically solving the recurrence equations near breakdown and beyond. Moreover, no analytical model has yet been developed that can capture the bandgap-boundary effects encountered in

heterostructure APDs. Such boundary effects include the initial energy of injected carriers and the layer-dependent profile of the dead space in the multiplication region.

In this paper, we generalize the recurrence equations reported by McIntyre [7] to include boundary effects associated with thin heterostructure APDs. This generalization draws from our recent work on the bandgap-boundary effects on avalanche multiplication noise [11]. The technique developed in this paper provides the means for predicting the probability of breakdown as a function of the applied reverse bias voltage for any heterostructure APD.

II. Analytical Model

Consider an APD with a multiplication region (possibly consisting of multiple layers) extending from $x = 0$ to $x = w$, and exhibiting an electric-field profile $\mathcal{E}(x)$. Assume that a parent electron is injected at $x = 0$, and that the electron has an initial energy E_0 which it acquires, for example, as it travels through a field gradient just before entering the multiplication region. According to basic principles of impact ionization [15], if the electron ionization threshold energy of the material is E_{ie}, then the injected electron must first travel an initial dead-space distance d_{e_0}, which is the solution to the equation $(E_{ie} - E_0) = \int_0^{d_{e_0}} q\mathcal{E}(y)\,dy$, before being able to impact ionize. (d_{e_0} is set to zero if $E_0 \geq E_{ie}$.) Furthermore, according to the hard-threshold dead-space multiplication model, the probability density function (pdf) of the distance ξ to the first impact ionization for the initial carrier is given by [11]

$$h_{e_0}(\xi) = \begin{cases} \alpha(\xi)\exp\left(-\int_{d_{e_0}}^{\xi}\alpha(y)\,dy\right), & \xi \geq d_{e_0} \\ 0, & \xi < d_{e_0} \end{cases} \quad (1)$$

where $\alpha(\cdot)$ is the nonlocalized position-dependent ionization coefficient of electrons, which can be calculated from the electric field through a material-dependent parametric model. Upon ionization, two electrons and a hole with zero initial kinetic energy are generated. Moreover, for an offspring electron, born at x with zero initial energy, the pdf of the distance ξ to the first impact ionization is given by [14]

$$h_e(\xi|x) = \begin{cases} \alpha(x+\xi)\exp\left(-\int_{d_e(x)}^{\xi}\alpha(x+y)\,dy\right), & \xi \geq d_e(x) \\ 0, & \xi < d_e(x) \end{cases} \quad (2)$$

where $d_e(x)$ is the dead space that it must first travel before being able to impact ionize. A similar argument applies to an offspring hole, in which case the pdf of the distance to the first impact ionization is

$$h_h(\xi|x) = \begin{cases} \beta(x-\xi)\exp\left(-\int_{d_h(x)}^{\xi}\beta(x-y)\,dy\right), & \xi \geq d_h(x) \\ 0, & \xi < d_h(x) \end{cases} \quad (3)$$

where $d_h(x)$ is dead space associated with a hole born at x. In [11], we describe how the dead-space profiles can be computed for a heterostructure. In the above model for ionization, we assumed that the value of the ionization coefficient beyond the dead space is dependent only on the material and the local electric field. A more realistic (but much more complex) model would consider the value to be a function of the history of the carrier. Despite its simplicity, when the above model is used in conjunction with the recurrence technique [1], [14], it has proven to be effective in predicting the low-noise behavior of thin APDs independently of the thickness of the multiplication region.

We now characterize the breakdown probability. Following the notation introduced in [1], let $Z(x)$ denote the total electron and hole population resulting from a parent electron born at x with zero initial energy. Similarly, let $Y(x)$ denote the total electron and hole population resulting from a parent hole born at x. Thus, for the case of electron injection (at $x = 0$), the APD gain G is given by $0.5(Z(0) + 1)$. Let $P_Z(x)$ be defined as the probability that $Z(x)$ is finite, and similarly, let $P_Y(x) \triangleq \mathrm{P}\{Y(x) < \infty\}$. McIntyre invoked a recurrence argument and characterized P_Z and P_Y through the following two nonlinear integral equations [7]:

$$P_Z(x) = \int_{w-x}^{\infty} h_e(\xi|x)\,d\xi + \int_0^{w-x} P_Z^2(x+\xi)P_Y(x+\xi) \cdot h_e(\xi|x)\,d\xi \quad (4)$$

and

$$P_Y(x) = \int_{x}^{\infty} h_h(\xi|x)\,d\xi + \int_0^{x} P_Y^2(x-\xi)P_Z(x-\xi) \cdot h_h(\xi|x)\,d\xi. \quad (5)$$

We now generalize these equations to the case when the parent carrier has nonzero initial energy.

Let $Z_0(x)$ be defined as $Z(x)$ with the exception that for the parent electron at x, the distance ξ to the first impact ionization has a pdf $h_{e_0}(\xi)$ [as defined in (1)]. The key observation here is that upon the first ionization of the injected electron, the two newly-created electrons and hole will have zero initial energy, independently of the initial energy of their parent electron. Consequently, conditional on the initial ionization occurring at ξ, $Z_0(x)$ is finite if and only if each one the two offspring electrons and the offspring hole produces a finite number of offsprings. Thus after averaging over all possible ξ, we obtain the following modified recurrence equation for the probability that $Z_0(x)$ is finite:

$$\mathrm{P}\{Z_0(x) < \infty\} = \int_{w-x}^{\infty} h_{e_0}(\xi)\,d\xi + \int_0^{w-x} P_Z^2(x+\xi)P_Y(x+\xi) \cdot h_{e_0}(\xi)\,d\xi. \quad (6)$$

Hence, to calculate $\mathrm{P}\{Z_0(x) < \infty\}$, we must first solve for $P_Z(\cdot)$ and $P_Y(\cdot)$ according to (4) and (5), and subsequently use them in calculating the integral given by (6). This is the modified dead-space multiplication theory (MDSMT) for breakdown.

III. Results

To see the roles of the multiplication-region width and the initial energy of injected carriers on the breakdown characteristics,

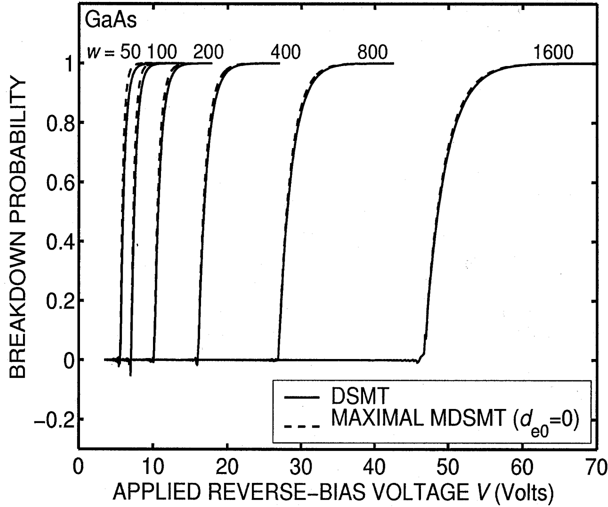

Fig. 1. Breakdown probability for GaAs as a function of the applied reverse-bias voltage for various multiplication-region widths. Solid curves represent the DSMT predictions. Dashed curves represent the maximal-MDSMT predictions.

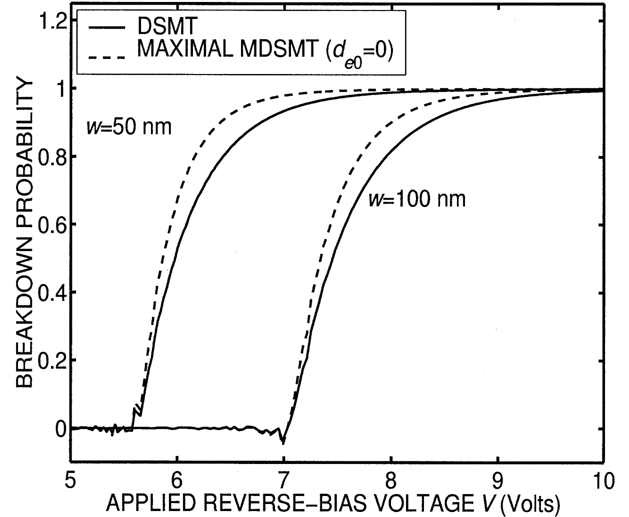

Fig. 2. Magnification of Fig. 1 for $w = 50$ nm and $w = 100$ nm.

we numerically solved (4)–(6) and computed the breakdown probability as a function of the applied reverse-bias voltage for GaAs. In these calculations, we assumed a constant electric-field profile within the multiplication region and used the simple approximation $V = \mathcal{E}w$ for the reverse-bias voltage. The parameters for the nonlocalized electron and hole ionization coefficients for GaAs were taken from Saleh *et al.* [4]. Two sets of results were generated for each width. In the first set, we assumed that the injected carrier possessed no initial energy (i.e., $E_0 = 0$), in which case the results were obtained by solving (4) and (5) and the breakdown probability was calculated using $1 - P_Z(0)$. We refer to this set of results as the DSMT predictions. In the second set of results, we assumed that the initial energy was in excess of the electron ionization energy E_{ie}, in which case the initial dead space d_{e_0} was set to zero. These results were obtained by inserting $P_Z(x)$ and $P_Y(x)$, which were found for the first set, into (6), and the breakdown probability was calculated using $1-\mathrm{P}\{Z_0(0) < \infty\}$. We refer to this second set of calculations as the maximal-MDSMT predictions, as they reflect the maximum initial-energy effect. The predicted breakdown probabilities are shown in Fig. 1 for $w =$ 50, 100, 200, 400, 800, and 1600 nm. As expected, reducing w serves to cause breakdown to occur at a lower reverse bias. Moreover, for a fixed w, the initial energy of injected carriers causes the breakdown to occur more abruptly, as can be seen from the magnified plots in Fig. 2. This new result can be explained as follows. The initial energy of an injected carrier enhances the probability of the initial impact ionization occurring in the onset of the multiplication process (i.e., near the edge of the multiplication region). This, in turn, will enhance the breakdown probability as each of the offspring electrons will have a higher chance of breakdown as they have a longer distance to travel. Note that the breakdown voltage V_B is the voltage corresponding to the point when the breakdown probability begins to exceed zero. We also note that the calculated values of the breakdown probability near breakdown are sensitive to precision error (resulting from discretizing the recurrence equations); however, the calculated values rapidly stabilize beyond the breakdown voltage. We emphasize that in our calculation we used nonlocalized ionization coefficients [4], [5]. The use of the bulk, or so-called localized, ionization coefficients [16] cannot be justified for our technique, as they are not consistent with the dead space theory. It was observed that attempting to use such localized coefficients in the current recurrence technique can lead to unstable solutions.

We also observe from Fig. 2 that both the DSMT and the maximal-MDSMT models predict a more abrupt transition for a thin device than a thick one. However, in order to see the magnitude of this increase in transition abruptness relative to the breakdown voltage, we normalized the transition abruptness by the breakdown voltage. To do so, we calculated the breakdown steepness factor $\Delta V/V_B$, where ΔV is the voltage difference corresponding to the transition in breakdown probability from 0.05 to 0.95. (The smaller the steepness factor, the more abrupt the transition is.) Fig. 3 shows the behavior the steepness factor as a function of w. According to DSMT model, as w decreases, the steepness factor increases, and hence the transition from stable to unstable becomes *relatively* less abrupt. However, according to maximal-MDSMT calculations, the steepness factor is almost invariant as w decreases. Hence, the initial energy of injected carriers serves to preserve the stable-to-unstable transition characteristics, especially for low values of w. This is a very desirable feature: it indicates that the reduction in the breakdown voltage with decreasing device thickness can be made available without compromising the relative abruptness of the breakdown transition.

IV. Comparison With Experiments

The purpose of this section is to validate our predictions of the breakdown voltage for thin APDs. Moreover, since in this paper, the breakdown voltage is extracted directly from the predicted behavior of the breakdown probability as a function of the applied bias, agreement of the breakdown-voltage predictions with experiment will also serve to partially validate the correctness of our model for the breakdown probability. According to our

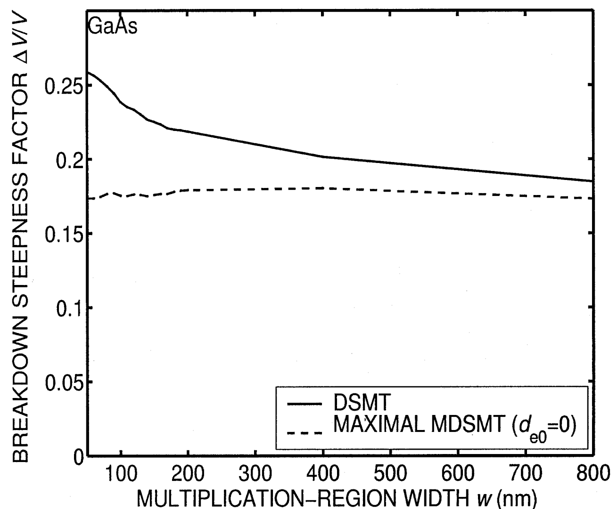

Fig. 3. Characteristics of the transition steepness factor $\Delta V/V$ for GaAs. This factor is zero when the transition is abrupt.

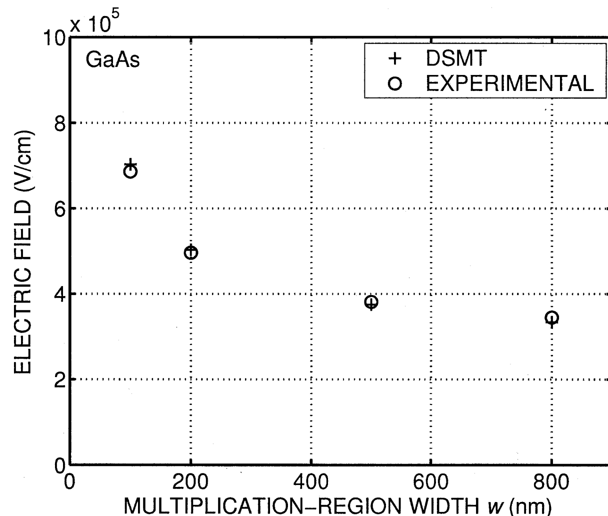

Fig. 4. DSMT predictions and experimental values of the breakdown voltage for various GaAs APDs.

knowledge, there is no relevant experimental data available on the probability of breakdown; thus, our predictions regarding the steepness of the breakdown probability cannot be experimentally verified at this time.

The predicted breakdown voltage V_B was compared with the measured values obtained for homojunction GaAs APDs. These homojunctions, which were described in detail in [2], have been shown to exhibit negligible initial-energy effect [11]. We, therefore, only considered the DSMT predictions and not the MDSMT in this case. For various multiplication-region widths, the predicted and experimental values for the breakdown voltage were, respectively, 7.03 and 6.86 V (at $w = 100$ nm), 10.06 and 9.92 V (at $w = 200$ nm), 18.75 and 19.05 V (at $w = 500$ nm), and 26.72 and 27.60 V (at $w = 800$ nm). The corresponding breakdown electric-field values are shown in Fig. 4, demonstrating the very good agreement between the DSMT predictions and experiment. Such good prediction of the breakdown voltage was also demonstrated earlier using a different technique (which does not yield the breakdown probability) based on impulse-response considerations [9]. We emphasize that the excellent agreement with experiment was obtained as a direct result of using the independently-calculated ionization coefficients and threshold energies [4] in the breakdown recurrence theory without introducing any model adjustments or auxiliary parameters to fit the data.

We also applied the theory to two heterostructure APDs. The first device was a GaAs–$Al_{0.6}Ga_{0.4}As$ heterostructure, where the multiplication is confined to the GaAs layer and $w = 130$ nm. (Electrons are injected from the $Al_{0.6}Ga_{0.4}As$ p-layer into the GaAs i layer.) It was previously shown that at high electric fields (>670 kV/cm), the initial-energy effect for this device reached its maximal limit, in which case the initial dead space vanished for the injected electron [11]. The second device was also a GaAs–$Al_{0.6}Ga_{0.4}As$ heterostructure APD, but for which the multiplication takes place in two adjacent $Al_{0.6}Ga_{0.4}As$ (100 nm) and GaAs (30 nm) i layers. (Electrons are injected from an $Al_{0.6}Ga_{0.4}As$ p-layer into the $Al_{0.6}Ga_{0.4}As$ i layer.) The width of the overall multiplication region for the second device was thus 130 nm. (For $Al_{0.6}Ga_{0.4}As$, the parameters for the ionization coefficients were taken from Tan *et al.* [5].) The effect of initial energy in this device was shown to be very modest, resulting in a dead-space reduction of no more than 10% at $\mathcal{E} = 800$ kV/cm [11].[1] We performed three sets of calculations for each device: These included the DSMT and the maximal-MDSMT predictions, as well as the MDSMT predictions, in which case the actual initial energy of injected carriers was used. These initial energies were previously calculated from the electric-field profile for each device, which were calculated using Medici software according to the doping profiles obtained from secondary ion mass spectroscopy (SIMS) [11]. (A lookup table was generated relating the applied bias voltages to the electric-field profiles.) The predictions for the first heterostructure are shown in Fig. 5. Consistent with the homojunction GaAs results, the maximal-MDSMT model predicts a more abrupt transition from sub-breakdown to breakdown than the DSMT. Moreover, the maximal-MDSMT and MDSMT curves are almost overlapping, since the initial dead space is almost nonexistent. In contrast, the behavior is different for the second heterostructure, as shown in Fig. 6, where the MDSMT and DSMT predictions are almost indistinguishable. This is because the initial energy in the second device is negligible in comparison to the ionization threshold for $Al_{0.6}Ga_{0.4}As$. As for the breakdown voltage V_B for these two heterostructures, the MDSMT predictions for the first and second heterostructure APDs were 8.37 and 11.00 V, respectively, whereas the corresponding experimental values were 8.35 and 12.43 V.

We finally make the comment that the initial-energy effect considered in this paper does not affect the breakdown voltage, as can be seen from Figs. 1, 2, 5, and 6. This behavior can be explained from the formulas given in (4) and (6). First, note that $\mathsf{P}\{Z_0(x) < \infty\} = 1$ precisely when the integrands $P_Z(x)$ and $P_Y(x)$ (in the second integral) are unity over the support of

[1]All the devices considered in this paper were fabricated and tested at the Microelectronics Research Center at the University of Texas in Austin. Further details on the structure of these two APDs are included in [11].

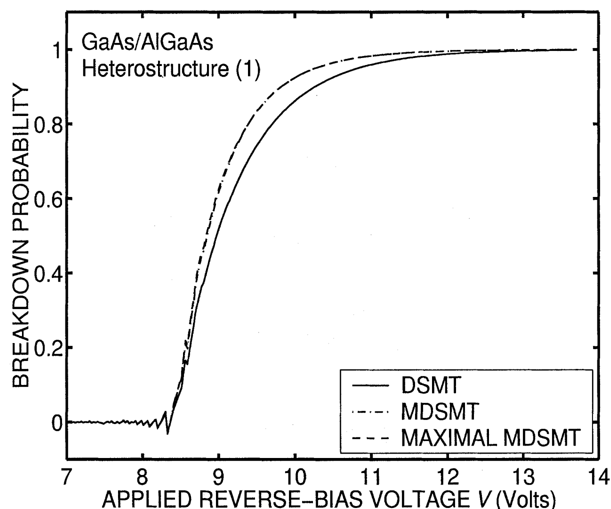

Fig. 5. Breakdown probability versus applied reverse-bias voltage for the first heterostructure GaAs–$Al_{0.6}Ga_{0.4}As$ APD, which has a GaAs multiplication-region width of 130 nm. Three separate curves are shown representing the DSMT-predictions (solid), the MDSMT predictions (dotted-dashed), and the maximal-MDSMT predictions (dashed).

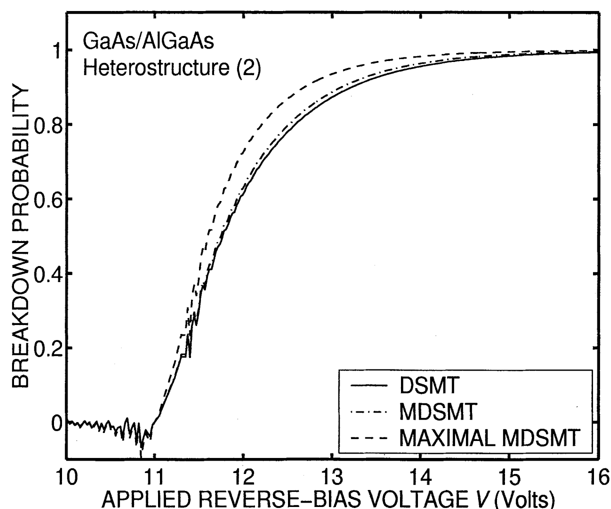

Fig. 6. Same as Fig. 5 but for the second GaAs–$Al_{0.6}Ga_{0.4}As$ heterostructure, which has a two-layer $Al_{0.6}Ga_{0.4}As$–GaAs multiplication region width total width of 130 nm.

$h_{e_0}(x)$ (i.e., the range over which $h_{e_0}(x)$ is nonzero). In such a case, the relationship (4) necessarily implies that $P_Z(0) = 1$ as long as the support of $h_{e_0}(x)$ includes the support of $h_e(x)$, which is the case here since $h_{e_0}(x)$ involves a reduced dead space. Thus, $\mathsf{P}\{Z_0(x) < \infty\} = 1$ implies $P_Z(0) = 1$, which means that stability in the presence of the injected-carrier's initial energy implies stability in the absence of the initial energy. Conversely, suppose that $\mathsf{P}\{Z_0(x) < \infty\} < 1$, which corresponds to instability in the presence of the initial energy. Then, it follows from (6) that $P_Z(x) < 1$ or $P_Y(x) < 1$ within the support of $h_{e_0}(x)$. In such a case, we deduce from the relationship given in (4) that $P_Z(0) < 1$, since the support of $h_{e_0}(x)$ includes the support of $h_e(x)$. This shows that $\mathsf{P}\{Z_0(x) < \infty\} < 1$ implies $P_Z(x) < 1$, or equivalently, $P_Z(x) = 1$ implies $\mathsf{P}\{Z_0(x) < \infty\} = 1$, which means that stability in the absence of the injected-carrier's initial energy implies stability in the presence of the initial energy. Thus, we have proved that stability, and thus the breakdown voltage, is independent of the initial energy of injected carriers.

V. Conclusions

In this paper, we showed that the breakdown characteristics are enhanced in thin APDs. In particular, reducing the thickness of the multiplication region not only serves to reduce the breakdown voltage, as has been observed previously, but it also makes the transition from sub-breakdown to breakdown more abrupt on an absolute scale (the transmission abruptness relative to the breakdown voltage is reduced, however). This feature is particularly desirable for Geiger-mode operation of the APD, as the likelihood of breakdown is enhanced, which leads to enhanced detection and less sensitivity to bias fluctuations. Moreover, the absolute and relative abruptness of the transition can be further enhanced if injected photogenerated carriers have an initial energy comparable to the ionization threshold. Such a phenomenon can occur in heterostructure APDs, and can be manipulated through careful bandgap engineering and doping. APD designs that have the potential for accentuating the initial-energy effect (e.g., certain separate-absorption-charge-multiplication structures) are thus expected to exhibit improved breakdown characteristics.

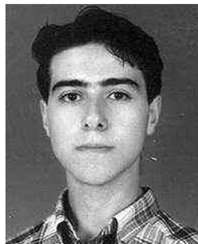
Majeed M. Hayat (S'89–M'92–SM'00) was born in Kuwait in 1963. He received the B.S. degree (*summa cum laude*) in electrical engineering in 1985 from the University of the Pacific, Stockton, CA, and the M.S. and Ph.D. degrees in electrical and computer engineering in 1988 and 1992, , respectively, from the University of Wisconsin-Madison.

From 1993 to 1996, he was with the University of Wisconsin-Madison as a Research Associate and Co-Principal Investigator of a project on statistical minefield modeling and detection, funded by the Office of Naval Research. In 1996, he joined the Department of Electrical and Computer Engineering, University of Dayton, Dayton, OH. He is currently an Associate Professor in the Department of Electrical and Computer Engineering, University of New Mexico, Albuquerque. His research interests include modeling and design of high-performance photodetectors, optical communication systems, statistical communication theory, communication networks, infrared imaging and sensors, and statistical signal and image processing.

Dr. Hayat is a recipient of the 1998 National Science Foundation Early Faculty Career Award. He is a member of SPIE and the Optical Society of America.



Ünal Sakoğlu (S'02) received the B.S. degree in electrical and electronics engineering in 2000 from Bilkent University, Turkey, and the M.S. degree in electrical and computer engineering in 2002 from the University of New Mexico, Albuquerque, where he is currently working toward the Ph.D. degree, researching nonuniformity-noise reduction algorithms for infrared focal-plane-array FLIR and spectral imagers.

Oh-Hyun Kwon was born in Seoul, Korea, in 1968. He received the B.S. degree in physics in 1995 from the University of the Hawaii, Manoa, and the M.S. degree in electrooptics from the University of Dayton, Dayton, OH. He is currently working toward the Ph.D. degree in electrical and computer engineering at the University of New Mexico, Albuquerque.

His research interests include modeling and fabrication of optoelectronic devices, with emphasis on avalanche photodiodes and quantum dot infrared detectors.

Shuling Wang received the B. S. degree in microelectronics from Beijing University, Beijing, China, in 1995, the M.S.E.E. degree from University of Notre Dame in 1999, and the Ph.D. degree from the University of Texas at Austin in 2002.

She is currently a post-doctorate Researcher in the Microelectronics Research Center at the University of Texas at Austin, working on high-speed, low-noise avalanche photodiodes.

Joe C. Campbell (S'73–M'74–SM'88–F'90) received the B.S. degree in physics from the University of Texas at Austin in 1969 and the M.S. and Ph.D. degrees in physics from the University of Illinois at Urbana-Champaign in 1971 and 1973, respectively.

From 1974 to 1976, he was with Texas Instruments, where he worked on integrated optics. In 1976 , he joined t AT&T Bell Laboratories, Holmdel, NJ. In the Crawford Hill Laboratory, he worked on a variety of optoelectronic devices including semiconductor lasers, optical modulators, waveguide switches, photonic integrated circuits, and photodetectors with emphasis on high-speed avalanche photodiodes for high-bit-rate lightwave systems. In 1989, he joined the faculty of the University of Texas at Austin as Professor of Electrical and Computer Engineering and Cockrell Family Regents Chair in Engineering. At present, he is actively involved in Si-based optoelectronics, high-speed avalanche photodiodes, GaN ultraviolet photodetectors, and quantum-dot IR imaging. He has co-authored six book chapters, more than 260 journal publications, and 160 conference presentations.

Dr. Campbell was recognized by AT&T as a Distinguished Member of the Technical Staff in 1985. He is a Fellow of the Optical Society of America. In 2002, he was elected a member of the National Academy of Engineering.

Bahaa E. A. Saleh (M'73–SM'86–F'91) received the B.S. degree from Cairo University, Cairo, Egypt, in 1966, and the Ph.D. degree from the Johns Hopkins University, Baltimore, MD, in 1971, both in electrical engineering.

He has been Professor and Chairman of the Department of Electrical and Computer Engineering at Boston University, Boston, MA, since 1994. He is Deputy Director of the National Science Foundation (NSF) Center for Subsurface Sensing and Imaging Systems. He is also co-director of the Quantum Imaging Laboratory and a member of the Boston University Photonics Center. He held faculty and research positions at the University of Santa Catarina, Brazil, Kuwait University, Max Planck Institute, Germany, the University of California–Berkeley, the European Molecular Biology Laboratory, Columbia University, and the University of Wisconsin–Madison, where he was a faculty member from 1977 to 1994, and served as Chairman of the Department of Electrical and Computer Engineering from 1990 to 1994. His research contributions cover a broad spectrum of topics in optics and photonics including statistical and quantum optics, optical communication and signal processing, nonlinear optics, photodetectors, digital image processing, and vision. He is the author of chapters in seven books, more than 180 papers in technical journals, and two books: *Photoelectron Statistics* (New York: Springer-Verlag, 1978) and (with M. C. Teich) *Fundamentals of Photonics* (New York: Wiley-InterScience, 1991), .

Dr. Saleh served as Editor-in-Chief of the *Journal of the Optical Society of America A* from 1991 to 1997, and is presently the Chairman of the Board of Editors of the Optical Society of America. He is the recipient of the 1999 Optical Society of America Esther Hoffman Beller Award for outstanding contributions to optical science and engineering education. He is a is Fellow of the Optical Society of America and the Guggenheim Foundation and a member of Phi Beta Kappa, Sigma Xi, and Tau Beta Pi.

Malvin Carl Teich (S'62–M'66–SM'72–F'89) received the B.S. degree in physics from the Massachusetts Institute of Technology (MIT), Cambridge, the M.S. degree in electrical engineering from Stanford University, Stanford, CA, and the Ph.D. degree from Cornell University, Ithaca, NY.

In 1966, he joined MIT Lincoln Laboratory, and then in 1967, the faculty at Columbia University, New York, where he served as a member of the Electrical Engineering Department (Chairman during 1978–1980), the Applied Physics Department, and the Columbia Radiation Laboratory. During his tenure at Columbia, he carried out extensive research in the areas of noise in avalanche photodiodes and fiber-optic amplifiers, photon statistics, and point processes, and the generation of squeezed light. In 1996, he was appointed Professor Emeritus of Engineering Science and Applied Physics at Columbia University. He has been teaching and pursuing research interests at Boston University, Boston, MA, as a faculty member with joint appointments in the Departments of Electrical and Computer Engineering, Physics, and Biomedical Engineering, since 1995. He is a member of the Quantum Imaging Laboratory, the Photonics Center, and the Center for Adaptive Systems. He also serves as a Consultant to government and private industry. He is most widely known for his work in photonics and quantum optics. His current efforts in photonics are associated with the reduction of noise in avalanche photodiodes and fiber-optic amplifiers; his efforts in quantum optics are directed toward developing imaging systems that make use of the correlation properties of entangled photon pairs generated in nonlinear optical parametric downconversion. He has authored or coauthored some 300 technical publications and holds two patents. He is the coauthor of *Fundamentals of Photonics* (New York: Wiley, 1991).

Dr. Teich served as a member of the Editorial Advisory Panel for *Optics Letters* from 1977 to 1979, as a member of the Editorial Board of the *Journal of Visual Communication and Image Representation* from 1989 to 1992, and as Deputy Editor of *Quantum Optics* from 1988 to 1994. He is currently a member of the Editorial Board of the journal *Jemnà Mechanika a Optika* and a member of the Advisory Board of the IEEE Press Series "Emerging Technologies in Biomedical Engineering." He received the IEEE Browder J. Thompson Memorial Prize for his paper "Infrared Heterodyne Detection " in 1969, a Guggenheim Fellowship in 1973, and the Memorial Gold Medal of Palacky University in the Czech Republic in 1992, and the IEEE Morris E. Leeds Award in 1997. He is a Fellow of the Optical Society of America, the American Physical Society, the American Association for the Advancement of Science, and the Acoustical Society of America, and a member of the Scientific Board of the Czech Academy of Sciences' Institute of Physics, Sigma Xi, and Tau Beta Pi.
